Early biogeographers have frequently compared species composition of different regions to evaluate their biogeographic affinities. This analysis, later scrutinized to include various quantitative methods, has revealed a common nonrandom pattern called nestedness, in which small biotas contain a nonrandom subset of the species in richer ones (Patterson and Atmar, 1986). Found in various taxonomic groups, nestedness is generally attributed to differential extinction and colonization, or a combination of both, though other factors may also be responsible. Differential extinction is arguably the prevalent mechanism of nestedness, especially in fragmented biotas. However, several biotas assembled by colonization also exhibited nested patterns. Some studies suggested that nestedness reflects differential dispersal ability coupled with geographical isolation. This suggestion can be tested by ranking the subsets (e.g., islands) according to their distance from the presumed source (e.g., mainland), and by examining the correlation between individual species contributions to the observed nestedness and species dispersal ability. Kadmon (1995) used this approach for woody plant species in seven man-made islands in a reservoir in eastern North America and confirmed that strong nestedness was attributable to geographic isolation and was correlated with dispersal ability. Wind-dispersed species showed no evidence of nestedness and species without particular adaptations for LDD showed the strongest nestedness. An equivalent pattern is seen in much broader spatial scales, where high dispersal abilities are associated with low levels of endemism, for example, in marine benthic invertebrates with teleplanic larvae such as the gastropod shown in Box 1. Similarly, the biotas of isolated islands such as Krakatau (*see* Colonization of Virgin Habitats), Galápagos, and Hawaii, are overrepresented by taxa having LDD mechanisms (but *see* The Geography of Dispersal), a characteristic termed disharmony to denote the lack of biotic elements that are conspicuously present on continents (Carlquist, 1974).

Another traditional approach to elucidate the role of dispersal in determining variation in geographical ranges among species is to test the relationship between some measures of species' dispersal ability and range size. Empirical tests of this relationship provided conflicting results. A key limitation of this approach lies in the difficulty of distinguishing cause and effect typical of correlation-based studies: Is the range size of a species small because of its low dispersal ability, or, as discussed in The Geography of Dispersal, is its dispersal ability low because of its small range?

During the 1970s and the early 1980s, the approach used in the study of historical biogeography shifted dramatically from explanations of the unique responses of individual groups to a quantitative and more rigorous analysis of general patterns. This progress was achieved mainly by the scholars of vicariance biogeography (*see* Introduction; Myres and Giller, 1988) who, based on Hennig's phylogenetic systematics and Croizat's panbiogeography, developed the area cladogram as a general technique for the analysis of biogeographic patterns. Area cladograms are branching diagrams representing history, similar to the traditional phylogenetic trees, but with the geographic areas replacing taxa at the terminal tips. Correspondence between phylogeny and independently derived geological history is taken to imply vicariance; dispersal is generally invoked to explain lack of correspondence. Congruence among area cladograms of different taxonomic groups from the same region more strongly implies a vicariant event and may be used to infer geological history in the absence of independent data.

In 1995, Juan Morrone and Jorge Crisci classified the historical biogeography methods into five groups: dispersalist, phylogenetic biogeography, panbiogeography, cladistic biogeography, and parsimony analysis of endemism. The methods of cladistic biogeography are the most diverse and most widely used (Morrone and Crisci, 1995). These approaches construct an area cladogram assuming vicariance as a null hypothesis. An alternative interpretation is presented in the book edited by Wagner and Funk in 1995 where simple area cladograms were produced for 25 taxonomic groups, including insects, spiders, birds, and flowering plants, of the Hawaiian Islands. The cladistic analysis was undertaken using various attributes, including morphological and anatomical characters, banding patterns on chromosomes, and DNA sequences from chloroplast, mitochondria, and nuclear ribosomes. Area cladograms were compared with several hypothetical patterns that represent historical scenarios that putatively generated the observed patterns, based on the geological history of the islands. The most frequent pattern was of dispersal from older to younger islands; several patterns were interpreted either as recent colonization from the mainland or as vicariant events within the archipelago. A book on the historical biogeography of Southeast Asia, edited by Hall and Holloway in 1998, provides another exemplary integration of ecological and evolutionary processes that account for the impact of dispersal and vicariance along with a profound analysis of the complex geological history of this region. Comparing phylogenetic versus geological divergence times, a general approach recently gained credit by new dating techniques such as Bayesian molecular clocks, further revealing that dispersal explanations might be preferred even if

the species dispersal ability is assumed to be poor. For example, seeds of the woody plant genus *Nothofagus* (southern beech) have no apparent transoceanic LDD mechanism but the 35 extant species exhibit strong disjunct distribution in the southern hemisphere; the genus was therefore considered to be an iconic example for the Gondwanan-breakup history of vicariant events. Yet, using relaxed molecular clocks based on chloroplast DNA, Michael Knapp *et al.* (2005) found that divergence of several species currently endemic to Australia or New Zealand occurred after the two landmasses have split. The most likely explanation for the current distribution of these species is therefore transoceanic LDD during the Late Tertiary.

Ronquist (1997) developed the dispersal–vicariance analysis (DIVA), which reconstructs the ancestral distributions of the species in a given phylogeny without any prior assumption about the form of area relationships and allowing dispersal and extinction. The optimal ancestral distributions are those that minimize the number of dispersal and extinction events required to explain the pattern. The number of dispersal events is underestimated because similar distributions between species are interpreted as sharing vicariant history, though this is not necessarily the case. This method disentangles some important methodological and conceptual restrictions of previous methods and is currently the most widely used method in historical biogeography. Although DIVA, as its name implied, has been considered as a potential bridge between vicariance and dispersal biogeography, this method and similar event-based methods such as tree fitting, strongly bias against dispersal and extinction events in favor of vicariance and local speciation (within the original area).

Nevertheless, analysis of 23 phylogenetic datasets of plants from the southern hemisphere revealed that most (18) of them were consistent with the dispersal rather than the vicariance explanation (Sanmartín *et al.*, 2007). Interestingly, although most of the reconstructed dispersals from Australia to New Zealand fitted the predicted eastward transport by the western wind drift and the Antarctic circumpolar ocean current, the reconstructed dispersals from New Zealand to South America were more frequently in the opposite direction. In another example, Voelker (1999) reconstructed the ancestral distributions and the direction of dispersal events in the pipits (*Anthus* spp.), small songbirds taxonomically related to the wagtails that occur on all continents. The results show that 16 dispersal events are required to explain the biogeographic pattern of the 40 species analyzed. The reconstructed map of colonizations from the postulated ancestral area in central Asia (Figure 7) shows broad intercontinental movements, suggesting that dispersal played an important role in the distribution of this group.

The parsimony principle underlying DIVA and other event-based methods necessitates that the parameters representing processes such as dispersal will be fixed beforehand and not estimated directly from the data. To overcome this and other limitations, several maximum-likelihood methods (e.g., Ree and Smith, 2008) and Bayesian approaches (e.g., Hickerson and Meyer, 2008) have recently been developed and applied to elucidate the role of dispersal and vicariance in historical biogeography. In 2009, Juan Santos and colleagues, for example, used relaxed Bayesian clock analyses and a maximum-likelihood dispersal–extinction–cladogenesis method to reconstruct the biogeography of the poison frog clade

Figure 7 Major intercontinental and continent-to-island colonizations (arrows) by pipits (*Anthus*) from a postulated ancestral area in central Asia (large circle). The approximate time of each colonization event is given either in million years (numbers close to the arrowheads) or is defined as recent (single species that have dispersed onto another landmass). Reproduced from Voelker G (1999) Dispersal, vicariance, and clocks: Historical biogeography and speciation in a cosmopolitan passerine genus (*Anthus*: Motacillidae). *Evolution* 53: 1536–1552, with permission from Wiley.

(Dendrobatidae). The Amazonian center-of-origin hypothesis was rejected in favor of a complex set of vicariance and dispersal events, both out and into Amazonia, mostly from the Andes where significant *in situ* diversification took place.

Modeling

Mathematical models are useful tools for exploring the role of dispersal in the process of range expansion and for predicting expansion dynamics. A comprehensive study from various fields such as genetics, epidemiology, and biological control has led to the development of highly diverse mathematical approaches of varying complexity to modeling movement and spatial population dynamics. These models include dispersal models that focus on the movement alone and reproduction–dispersal models that incorporate dispersal with local population growth to model the spatial spread of populations. The rich literature on this subject was reviewed and summarized by Turchin (1998, p. 73), who concluded with the following prognosis: “the theory is well developed, and appears to be ready to incorporate whatever quantitative information about movement we can provide.” Surprisingly, biogeographers have generally overlooked this progress, despite its obvious relevance and potential contribution to the field. A brief overview of some important dispersal and expansion models follows; details can be found in Mollison (1995), Shigesada and Kawasaki (1997), Turchin (1998), and Okubo and Levin (2001).

Dispersal Models

Dispersal models include phenomenological (empirical curve fitting), diffusion, individual-based, and mechanistic (transport) models. The basic objective of these models is to estimate the probability distribution of dispersal distances, which is often given in a standardized functional form called the dispersal kernel (Nathan and Muller-Landau, 2000). A classic dispersal model used in biogeography is the stepping-stone model of MacArthur and Wilson (1967), which assumes that a disseminule moves in a constant direction from one island to another and has a constant probability m per unit time of landing (cessation of movement). Mathematically, these assumptions lead to a widely used phenomenological model – the negative exponential function – in which the probability to disperse to distance x decreases with x at a rate equal to $\ln(m)$. Other widely used phenomenological dispersal models follow the Gaussian distribution and the inverse power law. The Gaussian models usually underestimate observed dispersal data, which almost universally exhibit a leptokurtic distribution (see The Evolutionary and Population Genetics Perspectives). The inverse power law has the problem of singularity (infinite density) at zero and hence its simple formulation cannot be used as a dispersal kernel.

Another set of dispersal models that is likely to prove beneficial to dispersal biogeography is that of the mechanistic models, which simulate the process by a set of mathematical expressions that mimic the relationships and joint effects of the principal operative factors. For example, mechanistic models of seed dispersal by wind typically incorporate factors

such as the height of release, the seed free-fall velocity, and wind velocities (Nathan *et al.*, 2001). Although complicated to develop and parameterize, these models have the decisive advantages of actually predicting, rather than of merely fitting, changes in disseminule densities with distance, and of potential generalization to other systems. From the biogeographic perspective, special attention should be paid to the tail of the distribution, since LDD is disproportionately important in jump dispersal and range expansions. Mathematically, it has been shown that kernels differing significantly in their tails yield dramatically different rates of population spread, even if they have the same mean. Turchin (1998) summarized the relationships between dispersal models and the types of population spread, focusing on the tail of the dispersal kernel. If the tail of the dispersal kernel drops off exponentially or faster with distance (e.g., Gaussian tails that are predicted by simple diffusion), then we should observe linear spatial spread in which the range is expanded at a constant rate during each time step. If the tail drops off slower than the exponential tail, as in the so-called “fat-tailed” kernels, the type of spatial spread depends on whether the variance of the kernel is finite or infinite. In both cases, the rate of spatial spread accelerates (i.e., increases with successive time steps), but the former reaches an asymptote of a constant expansion rate, whereas the latter continues to increase. Thus, fat-tailed dispersal kernels lead to jump range expansion, whereas exponential and thinner tails lead to gradual range expansion (see The Biogeographic Perspective). Since data on LDD are rare, the assumptions of the characteristics of the distribution’s tail cannot yet be tested; at the same time it is clear that extrapolating beyond the observed range is questionable.

The need to implement “fat-tailed” phenomenological and mechanistic dispersal models is now well established in dispersal research. Yet, the task of applying and testing models of LDD is inherently more complicated than for short-distance dispersal, despite recent technical developments with miniature remote sensing techniques and molecular markers (Nathan, 2006). Important attempts to model the mechanism of LDD has been made for the wind dispersal of aerial plankton (Kuparinen, 2006) and seeds (see Nathan *et al.*, 2011b for review), based on the knowledge of atmospheric dynamics. Similarly, knowledge of sea currents and the winds that drive them can be used to predict the trajectories of passively dispersed marine biota (Cowen *et al.*, 2006). Nevertheless, some enigmatic LDD phenomena, such as the dispersal of seeds and invertebrates by migratory birds and dispersal of various propagules by extreme weather events such as hurricanes remain out of reach for both modelers and field researchers (Nathan *et al.*, 2008b).

Reproduction–Dispersal Models

The dispersal models that have been discussed thus far are useful tools to understand the general relationships between dispersal and spatial spread. Reproduction–dispersal models, however, are more realistic since they consider the effects of birth and death during the process of range expansion. The simplest reproduction–dispersal models are reaction–diffusion models; and the simplest of those,

introduced to biologists by Skellam (1951), model dispersal as random diffusion and local population growth as exponential increase

$$\frac{dN}{dt} = rN + D \left[\frac{\partial^2 N}{\partial x^2} \right]$$

where N is the population size, t is time, and x is the distance from the source; the two parameters are D , the diffusion coefficient, and r , the intrinsic rate of population growth. Earlier, Fisher (1937) used a nonlinear variant of this equation in which the unbounded exponential growth (rN) is replaced by asymptotic logistic growth ($rN(1 - N/K)$), where K is the equilibrium population size (or carrying capacity). As shown by Fisher, this model predicts, as does Skellam's model, a constant asymptotic front velocity equal to $2\sqrt{rD}$. This type of gradual range expansion does not incorporate the effect of LDD events. Tests of reproduction–dispersal models against observed expansion pattern, starting from Skellam's (1951) pioneering study, have frequently showed that the simple reaction–diffusion approach cannot provide a general description for range expansion. For example, Andow *et al.* (1993) found approximately linear rates of spread in two case studies and accelerating rates of spread in two others. Even for the cases that show linear rates, such as that of muskrats (*see The Spread of Alien Species*), there was significant variation in space and time. Expansion rates of muskrats were lower in the first 2–3 years, possibly because of Allee effects (*see Ecological Opportunity: Postdispersal Establishment*), and the average rates range from 0.9 to nearly 80 km yr⁻¹. Thus, reaction–diffusion models are best used as a primary null analysis of expansion patterns, followed by more complex approaches, including stratified diffusion, interacting particle systems, and spatial contact models. These models incorporate both short- and long-distance dispersal and thus are able to predict patterns of jump range expansion as well.

Biogeographic and Evolutionary Consequences of Dispersal

Dispersal, evolution (adaptation and speciation), and extinction are the fundamental processes in biogeography. Together, they determine the geographical distribution of organisms. Dispersal biogeography focuses on the effects of dispersal on evolution and especially on speciation, both within a lineage and for other lineages. The following section outlines some principal relationships; more details are given in related articles on speciation and extinction in this encyclopedia.

Speciation

Speciation is the process by which new independently evolving lineages (species) arise from a single ancestral lineage. In general, efficient dispersal between populations (patches) increases the rate of gene flow between them and hence tends to reduce genetic differentiation and to restrain speciation. In contrast, inefficient dispersal between existing populations leads to geographic isolation and tends to increase genetic

differentiation and to promote speciation. This type of speciation, called allopatric speciation, is considered to be the most frequent one. Jump range expansion occurs with very low probability (*see The Biogeographic Perspective*) and is thus unlikely to be followed by additional dispersal; this isolation thereby causes rare dispersal events (in this context also called founder events) to be relevant to allopatric speciation. The adaptive radiation of Darwin's finches in the Galápagos Islands is one of the many examples of allopatric speciation that has resulted from dispersal events. However, as discussed in the Introduction, a dispersal barrier may divide a previously continuous distribution. Hence, allopatric speciation may also result from a vicariant event.

A second way in which dispersal affects speciation requires the opposite conditions. The breakdown of a dispersal barrier, and the following biotic interchange (*see Removal of Barriers*), brings organisms to dissimilar environments and thus opens new chances for diversification. The colonization of North American mammals during the Great American Interchange (*see Removal of Barriers*) was followed by extensive diversification in South America. In the same manner dispersal events cause speciation. They affect the genetic structure within the species range, sometimes to the point that the populations are evolving independently, and can be considered as distinct species. Theoretical models and molecular studies have shown clear effects of LDD on the spatial structure of the genetic variation within a species during the postglacial expansion of European and North American biota (*see Holocene Postglacial Spread*). As predicted by models, jump range expansion well ahead of the “normal” advancing wave generates large patches of low genetic variation, due to the so-called founder effects; consequently, genetic diversity decreases from south to north.

Extinction

Limited dispersal is associated not only with higher rates of speciation (*see Speciation*) but generally also with higher rates of extinction. This phenomenon has been observed at various spatial scales. For example, the fossil record shows that gastropods with planktonic larval dispersal, typically have high LDD capacity (**Box 1**), tend to have larger geographical ranges and to persist for longer periods of time than do those with nonplanktonic larvae, which are dispersed locally. A similar phenomenon is observed at regional scales, where populations with higher rates of immigration persist longer due to increased population size and higher levels of genetic variability, which counteracts the deleterious effects of inbreeding. This so-called rescue effect has been observed in a variety of organisms. The very similar notion of source–sink dynamics attributes a longer persistence time to populations in unfavorable sink habitats (where death rates exceed birth rates) due to a rescue effect from populations in favorable source habitats (where birth rates exceed death rates). Another relevant term “mass effect” emphasizes the contribution of rescue effects to the breeding stock. The regional framework of populations subjected to local extinction and recolonization is treated in metapopulation models in which dispersal plays a critical role.

Although dispersal tends to reduce the probability of extinction of the same species, dispersal, as immigration, may have the opposite effect on other species inhabiting the recipient site. Around 1950, the brown tree snake (*Boiga irregularis*) of Australia and Southeast Asia was accidentally introduced to the Pacific island of Guam. This fairly large (up to 3 m) snake, which eats bird eggs from nests either on the ground or in trees, caused the extinction of most of the native birds and the decline of almost all other native terrestrial vertebrates. Despite this and other spectacular examples of massive extinction caused by colonization of a given species, most colonization events appear to have minor consequences. The consequences of colonization of one species to the persistence of other species depend on the species' biology and on postdispersal processes, however, dispersal is the ultimate cause of such extinctions, since it determines whether the prerequisite species is present. Though the particular dispersal mechanisms should not matter to the severity of such incidents, it is noteworthy that in most documented cases dispersal was related to human activity.

Applied Dispersal Biogeography

Biogeography in general, and dispersal biogeography in particular, has an important role in managing the world's biodiversity. The processes currently threatening the world's biota typically act on large scales, and the movement (or lack thereof) of organisms is a key process. Dispersal is strongly involved with issues such as invasions, introductions, fragmentation, climatic changes, design of nature reserves, and control of gene flow; it is hard to imagine any issue of applied biogeography that is not related to the dispersal process. Thorough discussions of these practical aspects of biogeography can be found in Williamson (1996), Brown and Lomolino (1998), and Spellerberg and Sawyer (1999); this section outlines some major principles of applied dispersal biogeography.

Applied dispersal biogeography deals with all aspects of dispersal that are involved with the management of the Earth's biota and aims to predict the causes and the consequences of dispersal events. The main threats to global biodiversity involve excessive LDD of elements alien to ecosystems and insufficient dispersal of native species, for example, because of habitat fragmentation (Trakhtenbrot *et al.*, 2005). The mathematical models described above (see Modeling) are efficient tools on small scales. Although our ability to predict LDD continues to improve, much still remains to be done, especially the testing of these predictions. LDD has a substantial stochastic component, which will always remain somewhat unpredictable. However, since most LDD events with harmful consequences are related to human activity, our predictive ability of anthropogenic arrivals may be better than for natural arrivals. Even unintentional dispersal such as that of the brown tree snake to Guam (see Extinction; Box 1) is to some degree predictable and controllable. As emphasized earlier, the variation among organisms in dispersal ability is enormous (Box 1); responses to dispersal barriers and dispersal routes also vary considerably (see Physical Access: Dispersal Barriers

and Dispersal Routes). Mathematical models, especially mechanistic ones (see Dispersal Models), can be used to predict dispersal of particular species using knowledge of the species-specific dispersal traits (Box 1) and the effect of environmental factors on dispersal (see Physical Access: Dispersal Barriers and Dispersal Routes and The Geography of Dispersal).

The invasion of muskrats to Europe (see The Spread of Alien Species) illustrates these points. The muskrat's arrival was related to human activity and the animal's escape was controllable; expansion rates are predictable through simple mechanistic models based on dispersal and reproduction (see Reproduction–Dispersal Models); the variation in expansion rates was related to habitat-related factors (see The Geography of Dispersal and The Spread of Alien Species) and was therefore also predictable. The large number of escapes and the initial slow rates of expansion demonstrate the importance of propagule pressure (see The Spread of Alien Species) and probably of Allee effects (see Ecological Opportunity: Postdispersal Establishment) as well. Attempts to control this expansion – mostly extensive trapping campaigns – have failed in continental Europe, but have succeeded in Britain and Ireland. Mark Williamson (1996) suggested that the relatively early response in the British Isles, before the muskrats spread too far and built overly large populations, along with presumably inferior climatic matching that would have led to lower reproduction rates, are possible reasons.

Synthesis

The importance of dispersal in determining the geographic distribution of organisms has been emphasized by Darwin and other dispersalists. These views have been seriously questioned by their opponents, who argue that vicariant events are the principal determinant of distributions. Clearly, both processes occur and their effects vary between species both in space and in time. The term “dispersal biogeography” is currently restricted to the arguments of extreme dispersalists concerning LDD and disjunct distributions. The broader and more fruitful usage of this term adopted here would be the study of the relationship between dispersal and the geographical distribution of organisms.

Dispersal is a widespread phenomenon occurring in nearly all organisms. There is a high variability of dispersal ability in organisms, due to differences in their physiological, morphological, and behavioral traits and responses to environmental conditions. Dispersal is a key biological process at the ecological, evolutionary, genetic, and biogeographic levels, which differ in spatial and temporal scales. LDD, disproportionately important at the biogeographic level, is typically rare and very difficult to measure; it contains a large stochastic component but in many cases is a result of a specific mechanism and hence can be predicted. If followed by successful establishment, LDD can lead to abrupt long-distance colonization jumps. Short-distance dispersal is overwhelmingly important at the ecological level; at the biogeographic level, multiple short-distance dispersal events over a relatively long time, if followed by establishment, can lead to gradual range expansion. Patterns of speciation and extinction

are strongly affected by dispersal, demonstrating the broad biogeographic consequences of this process, which itself is also affected by geography.

The field of biogeography has gone through a dramatic shift since the publication of the first version of this article in 2001. Molecular tools to quantify genetic variation continue to improve and to become increasingly more cost-effective, providing data of much higher quality and quantity compared to what were available just a few years ago. Tools to analyze multiscale spatial patterns such as various Geographical Information Systems (GIS) techniques have been rapidly developed. The field of phylogeography, established 25 years ago to integrate the closely related, yet traditionally isolated, disciplines of population genetics and phylogenetic biology (Avice, 2009), has recently experienced a boost of developments of new statistical frameworks enabling us to test key hypotheses on the processes responsible for the observed phylogeographic patterns (Knowles, 2009). New tools enable tracking of smaller organisms for longer duration and new theoretical frameworks can associate studies across diverse movement phenomena into an integrated movement ecology paradigm (Nathan *et al.*, 2008a). Thus, one can scrutinize the complex set of intrinsic properties of individuals and their interactions with the biotic and physical environment that determine their dispersal and movements and eventually the distribution of species at both local and large scales. It is therefore the time now to develop synergies among all these and other exciting recent developments, to test challenging hypotheses about the role of dispersal and other movement phenomena in the evolution and distribution of biota. For some promising integrative frameworks, see the recent reviews of Spear *et al.* (2010), Chan *et al.* (2011), and Crisp *et al.* (2011).

Glossary

Between-habitat diversity Degree of dissimilarity in species composition between two habitats. The greater the number of species shared by two habitats, the lower the between-habitat diversity.

Metacommunity An assemblage of species in a patchy landscape, each species comprising a metapopulation in that its distribution shifts among habitat patches because the distribution is determined by colonization and extinction dynamics.

Metapopulation Group of subpopulations distributed among habitat patches in a landscape, each subpopulation being subject to periodic extinction and subsequent recolonization from other occupied patches.

Richness Simplest measure of diversity, represented by a count of the number of species in some ecologically

meaningful unit (community, metacommunity, region) without regard to variation in the number of individuals per species.

Saturation Upper limit to species richness within a community, set by species interactions, and independent of the pool of colonists to which that community is accessible.

Species pool Set of species that are able to colonize a habitat of interest.

Type I community An assemblage of species where the richness is a constant proportion of the number of species occurring in a larger geographic unit in which the community is embedded.

Type II community An assemblage of species where the richness is independent of the number of species in a larger geographic unit in which the community is embedded.

Two Perspectives on the Control of Community/Regional Diversity

Local Control of Species Richness

The Volterra–Gause Perspective

One of the most obvious and fundamental facts of ecology is that all species do not occur everywhere. Instead, each species has a unique distribution determined by its ecological context and evolutionary history. Nevertheless, species distributions overlap to varying degrees so that some places support more species than others do. Such variations in species richness have been a central issue in ecological and biogeographical studies at least since the turn of the century. Until recently, explanations focused mainly on processes operating within ecological communities over relatively short periods of time. This perspective arose out of a desire to add scientific rigor to ecological studies by focusing on mechanisms and ignoring history. A mechanistic approach made it possible to model ecological systems with simple equations and to test these models and their assumptions with carefully collected data.

One of the earliest truly influential models in community ecology was developed by Vito Volterra (and independently by Alfred Lotka) in the mid-1920s. This model is a set of simple differential equations describing competition between two species in terms of reductions in per capita population growth rates by interactions among individuals. When the model is analyzed at equilibrium, the outcome of competition (coexistence or competitive exclusion) is easily predicted from the intensity of interactions within species relative to those among species. If populations limit their own growth more than the growth of other populations, the two species will coexist. If they limit other

populations more than themselves, one will exclude the other. The model and its assumptions were later tested by G. F. Gause in laboratory systems comprising several species of protozoa. The tests lent strong support to the model, and as a result the so-called Volterra–Gause perspective has become a metaphor for the way in which ecologists think about control of species richness.

According to this perspective, species richness in a biogeographical region may indeed be determined in part by history. However, history has little relevance to the upper limits on local richness within communities. Instead local richness is limited primarily by species interactions (predation, parasitism, herbivory, competition, mutualism) in conjunction with abiotic conditions (water, nutrient, and energy availability, chemistry, temperature, disturbance). In other words, the outcome of interactions is determined in large part by the abiotic conditions in which they occur. For example, lower concentrations of a particular nutrient or lower water availability might favor one plant species in competition with another, but higher values of these factors might result in a reversal of competitive dominance. The number of species in the biogeographical region provides a species pool from which the local communities are drawn, and all species have the potential for colonizing all habitats in the region. Since habitats vary in their abiotic conditions and resident assemblages, only those species capable of coexisting in a given milieu will establish successfully. Differences in species richness thus result from differences in the abiotic template and species composition among habitats. In a recent series of publications from the early 1990s, James Drake has shown that the colonization order of species into a habitat can also have some effect, and communities can exhibit multiple stable points representing different levels of species richness.

A crucial element of this perspective that derives directly from the Volterra model is that communities exist at a dynamic equilibrium. For example, in the case of competition, population levels of the resident species are limited by resource availability and physical conditions. Thus, if sufficient time elapses and there are no perturbing disturbances to the community, the number of species will saturate at a level determined by the number of limiting resources and physical factors. At saturation, species are sufficiently similar in their resource use that finer subdivision of resources becomes increasingly difficult and new colonizations into the community must be accompanied by extinctions of current residents. If habitats throughout the region are all identical and saturated with species, then the total number of species in the region is limited to the total number coexisting within each identical habitat. That is, community and regional richness are identical and regional richness is limited by the same factors that limit local richness.

Since all habitats are not identical, species within the region have the option of partitioning habitats as well as resources and thus the same set of species will not occur everywhere in the region. Nevertheless, local processes are still limiting both local and regional richness, but limits on regional richness now result from interplay between species interactions and spatial habitat variation. The greater the number of habitats, the greater the between-habitat diversity and the greater the number of species in the region relative to those within a single community. Historical processes such as massive extinctions might reduce the number of species in the region for a time, and subsequent evolution, speciation, and dispersal might generate a new biota that differs from the previous one. However, the essential feature of this viewpoint is that given sufficient time, the imprint of history on species richness will fade, communities will fill up and become saturated, and processes operating locally will also limit richness regionally.

Even strict adherence to the Volterra–Gause viewpoint still allows for other factors to affect local and regional richness. All else being equal, larger localities and regions will support more species than smaller ones as predicted by the species–area relationship. In addition, some species within a region might be ecologically equivalent and thus might be able to substitute for one another within a given community type. Chance might determine what species occupies what particular community, in which case ecologically equivalent species could increase regional richness without affecting local richness. Finally, spatial interspersal of habitat types might allow species adapted to one habitat type to persist in an adjacent, less favorable habitat type by means of propagule flow. This so-called source–sink effect proposed by Ron Pulliam in 1988 would increase local richness in the less favorable habitat above that which would be self-maintaining in the absence of immigration. Although these factors may have important impacts on species richness, they do not alter the premise that the primary direction of control on species richness is from the local to the regional level.

An ecological community at equilibrium and not subject to vagaries of history evokes a powerful image that continues to influence modern ideas about species diversity. Robert MacArthur's (1972) book represents the pinnacle of this

viewpoint, although he recognized that the equilibrium assumption and local control of richness did not apply to all communities. There are clear recent demonstrations that species interactions have strong influences on community structure and might exclude species from the community (see Lawton, 1999, for a brief review). In short, the Volterra–Gause perspective has been a useful guide to a limited understanding of the mechanisms by which particular communities are structured. However, this understanding has led to few if any general patterns or rules that apply to most systems (Lawton, 1999).

Species–Energy Theory

Another view of local control of species richness comes from the ecosystem perspective, and has been termed “species–energy theory.” The theory was developed mainly by David Wright, David Currie, and Brian Maurer (1993). Species–energy theory posits that local and, ultimately, regional richness are limited by available energy within the local environment. Available energy limits local richness by placing ceilings on the population densities of individual species. As energy decreases, densities decrease, random extinctions increase, and local richness is reduced. Available energy can be scaled up to whole regions by multiplying the energy per unit area by the total area of the region. Thus, population densities and species richness over the whole region are also controlled by energy availability.

Although the theory in this simplified version posits local control of local and regional richness, it differs from the Volterra–Gause viewpoint in that species interactions are of secondary importance in limiting richness. Energy can have direct and independent effects on population levels to increase richness rather than mediating interactions among species. Interactions can be included in the model, but they are not necessary for limits on richness to occur. Species–energy theory is very similar to island biogeography theory, which proposes that species richness is a balance between colonization and extinction rates in a local habitat. Smaller habitats have higher per species extinction rates and thus lower species richness as predicted by the species–area relationship. The main difference between the two theories is that species–energy theory substitutes energy availability for area as the predictor of species richness.

A recent literature review by David Wright and others demonstrated that several proxy variables for energy availability (precipitation, potential or actual evapotranspiration, productivity) are indeed strong predictors of species richness for various taxonomic groups (Table 1). However, it is not clear whether energy is the direct cause of richness variation, or whether it simply covaries with other possible causes such as area effects, habitat heterogeneity, species interactions, and historical effects. It is also not clear whether the assumptions of the theory are always met in particular studies. For example, it is assumed that energy limitation should operate at the local scale where individuals of each species seek sufficient energy to persist in the community. However, it is at the scale of the local community that the correlation between energy and richness is weakest and most variable; the correlation is strongest at larger spatial scales (104–108 km²). It is also assumed that average population size and species richness

should increase together with available energy, but this is not always the case. In particular, David Tilman and Pacala have pointed out that plant systems often show an inverse relationship between per species population sizes and energy as predicted by the $-3/2$ power law, yet species richness commonly increases with energy in the expected way. Despite these limitations, energy can be a useful variable for estimating richness at larger scales because covariation is high regardless of the underlying causes, and because energy data (or proxies) are available for most geographic areas.

At more local scales, species interactions among resident populations may come into play, altering any potential increases in richness with energy availability. Such interactions might partially explain the more variable relationship between energy and richness within communities. Increased energy can lead to increased biomass of the total community, which in turn can lead to increases or decreases in average population density depending on the intensity of interindividual interactions and the size plasticity of the taxa involved. But it is the changes in the relative allocation of energy among species that are critical for predicting changes in richness. If allocation changes as energy availability increases, for example, caused by shifts in competitive superiority or ability to avoid predation, then the population densities of some species may increase while other species may be driven extinct. Richness can thus increase or decrease with increased energy depending on the circumstances. It is at this point that the species–energy theory

converges with the Volterra–Gause viewpoint since the environment is now mediating interactions among species.

The Diversity–Productivity Relationship

The idea that richness can change with energy availability in unpredictable ways has had a long history under the guise of the diversity–productivity relationship. Productivity is a measure of energy availability to the community and has been shown to affect local richness in contradictory ways; richness either increases, decreases, or shows no relationship with productivity depending on the assemblage. Recently it has been suggested that these contradictory relationships may just be incomplete segments of an overall hump-shaped, unimodal relationship over a broader range of productivity. In other words, richness peaks at intermediate productivity levels and declines toward the extremes. Different taxa can show richness peaks at different levels of productivity, resulting in unimodal curves that are displaced along the productivity spectrum. No ecological pattern is universal and, accordingly, contradictory relationships between richness and productivity need not always imply a truncated hump. Indeed, evidence for this possibility is currently limited at best (Waide *et al.*, 1999). Monotonic relationships may be just as frequent as unimodal ones. Nevertheless, the unimodal curve is a useful synthetic construct and it is sufficiently frequent to invite explanation. Moreover, the same explanations for each arm of the hump may apply equally well to monotonically increasing or decreasing relationships over a particular range of productivity.

It is not clear why richness shows this strange relationship with productivity, and the pattern remains one of the most important unsolved mysteries in community ecology. The hypothesis that productivity differences are directly responsible for the unimodal relationship assumes that productivity is uniformly distributed among sites. In other words, low-, medium-, and high-productivity environments occur with equal frequency. If medium-productivity sites are more frequent than low- or high-productivity sites, then the unimodal curve might just be a reflection of simple species–area effects. There is some evidence to suggest that this is not the case (Rosenzweig, 1995), but the possibility has not been extensively tested. At the very least, diversity–productivity correlations should be corrected for unequal area effects before a causative link between these variables is seriously considered.

Unimodal curves (as well as monotonically increasing or decreasing ones) can occur at different spatial scales (local, landscape, regional, continental), but their frequency changes as spatial scale increases. Monotonically increasing patterns are more common at larger scales and unimodal patterns are more common at local scales (Figure 1). Moreover, the mechanisms responsible for patterns at each scale probably differ (Waide *et al.*, 1999). Since the within-community, among-community, and local scales are where ecological processes become important, theories that consider changes in species interactions and local environmental conditions along productivity gradients are the most relevant.

The decline to the left of the hump may derive from increased environmental stress or the direct effects of energy reduction on population levels as proposed by species–energy theory. Other mechanisms, such as increases in disturbance rate, poor recovery from disturbance due to slower population growth rates, declines

Table 1 Energy-related and other factors which correlate with species richness

Factor cited	Correlations with species richness	
	Significant	Not significant ^a
<i>Energy-related factors</i>		
Mean annual heat and/or humidity variables	29	0
Productivity (sometimes est. as standing crop)	9	0
Nutrient, food availability	3	0
<i>Seasonality</i>	4	0
<i>Other factors</i>		
Habitat complexity, subdivision, microrelief	9	3
Disturbance	5	5 (2)
Environmental chemistry (pH, cations)	3	1 (1)
Isolation, peninsula effects	2	1 (1)
Diversity of food, prey	6	1
Regional richness	2	0
Time, historical factors	1	2 (2)
Competition, predation	0	1
Other	3	1

^aNumbers in parentheses indicate the number of correlations that were omitted from further analysis because no correlation coefficient was reported.

in territoriality, and environmental heterogeneity have also been suggested to play a role. The decline to the right of the hump may involve some form of interaction mediation among species, such as increased intensity of competition and predation or

increased population dynamic instability within food webs at high productivities. Such declines would then provide strong support for the idea that species interactions limit species richness in accordance with the Volterra–Gause viewpoint. However,

it is important to point out that richness declines in highly productive areas may also result from regional effects. For example if productive habitats are relatively rare, they are likely to be surrounded by larger, less productive areas and thus isolated from a large source pool of species adapted to productive conditions. As previously mentioned, area effects may also contribute to low richness. Regional effects must therefore always be taken into consideration when analyzing diversity–productivity relationships.

Tests that distinguish among these various theories are difficult to perform and have thus far been limited. Comparative approaches, although they require less disruption of the community, might not be able to distinguish among alternative theories unless natural “experiments” in which selected mechanisms are not operating can be found. Experimentation has better control of confounding variables, but care must be taken to provide enough time for all processes that contribute to changes in richness to ensure that they be allowed to respond to the manipulation. For example, in a 1999 review, Laura Gough and co-workers found that fertilization experiments consistently resulted in increases in inorganic nutrient concentrations, which in turn intensified species interactions in herbaceous plant communities. Fertilization increased productivity and reduced species richness across a broad range of community type, due primarily to increased dominance by one or a few species. These experiments certainly demonstrate the potential of interaction mediation to limit community richness. However, the relevance of such studies to richness declines in natural communities at highly productive sites is questionable. Fertilization reduces diversity even at poorly productive sites, where theory predicts that diversity should increase.

This anomalous result may be a consequence of the short-term nature and small spatial scale of such experiments. Species adapted to the higher productivities of the fertilized sites might not be able to reach them if they are isolated in space or time. More appropriate experiments should therefore manipulate the species pool to simultaneously test for the effects of productivity and the dispersal effects on richness. If pool limitation is the cause of the anomalous results, then experimentally boosted recruitment to low-productivity sites by an appropriate species pool should generate higher species richness with higher fertilization rates. Naturally, the species selected for the boosted recruitment should be well-adapted to the increased nutrient levels at the fertilized sites. High-productivity sites, on the other hand, should remain depressed in diversity owing to interspecific interactions. Some combination of comparative and experimental approaches will probably be required to solve the mystery of the diversity–productivity relationship. Regardless of the methods used, it is important that it be solved, since it represents one of the clearest possibilities that local richness is locally controlled. It also provides a single framework that subsumes both species–energy theory and Volterra–Gause processes.

Theory Doesn't Always Predict Local Control

Without question, the Volterra–Gause viewpoint has stimulated much research on the factors that control species richness. Nevertheless, the fundamental premise that local

processes control local and ultimately regional richness may be incorrect for many systems. Even the restrictive Volterra–Gause models do not always predict limits on species richness due to local mechanisms. After appropriate modification to incorporate some realistic features of environments and species, such as spatial heterogeneity, environmental fluctuations, nonlinear population growth responses to environmental change, and trade-offs among species in their ability to compete in different environments, the models often predict that there are no upper limits on local richness (Tilman and Pacala, in Ricklefs and Schluter, 1993). Moreover, the Volterra–Gause assumption that population levels are at equilibrium, may not commonly be met in natural communities. In a classic example, periodic disturbance can drive populations below equilibrium, where the outcomes of interspecific interactions are never fully realized. More species can thus invade than would be allowed by equilibrium population levels.

If real communities have any of these features, it is not likely that local richness will reach saturation as predicted by the simplest models. Evidence from real communities suggests that lack of saturation is indeed common. Lack of saturation raises the possibility that factors external to the community may ultimately determine local richness. As a consequence, the factors that determine regional richness must also be sought elsewhere. In the Volterra–Gause view, regional richness is limited by a combination of the number of species within saturated habitats and the number of habitats within the region. If communities within habitats are not saturated, control on regional richness cannot be exerted at the within-habitat scale. Moreover, the number of habitats within a region is not fixed and may be more an effect of the number and kinds of species in the region than a cause of richness limitation at the between-habitat scale (Rosenzweig, 1995). In other words, the more species there are in the region, the more finely habitats can be partitioned and the more distinct habitat types that can be identified. How, then, do differences in richness among regions arise? And what relevance do these differences have for local richness? An alternative to the Volterra–Gause viewpoint that addresses these questions is thus needed.

Regional Control of Richness

Regional Processes

The alternative view rests on an idea that actually predates the Volterra–Gause view, namely, that regional richness is set to a large degree by historical biogeographical factors. The importance of history is implicit in the traditional definition of a biogeographical region that relies in part on the presence of a distinctive native biota. The presence of large groups of indigenous species implies that the region has undergone a period of isolation and independent evolution. Thus, the numbers and kinds of species that occur across the region are determined to some degree by its unique historical development. These different histories might result in widely divergent species richnesses among some components of the biota, which in turn may be reflected in local communities. Under this scenario, local richness is not limited by species interactions as predicted by simple Volterra–Gause models, but

becomes some function of the number of species in the region that are able to colonize and persist in a given habitat. The richness of the community embedded within the region thus retains some of the region's historical signature.

The key prediction arising out of this scenario that distinguishes it from the Volterra–Gause model is that localities in richer regions can support more species than those in poorer ones even though the localities are environmentally similar. This is simply because species co-occurrences within localities are determined to some extent by the same factors that determine regional co-occurrence. In their 1991 book *Phylogeny, Ecology, and Behavior*, Brooks and McLennan pointed out that regional co-occurrence can come about via two processes: association by descent and association by colonization. In association by descent, two species can co-occur because their ancestors co-occurred. In other words, the community was assembled from ancestors in the distant past, and the species present today evolved *in situ* from members of the ancestral community, most likely by geographic isolation (Figure 2). The community is thus rich or poor because the region in which it is embedded was historically rich or poor. In association by colonization, two species can co-occur because one evolved elsewhere and migrated into the region. Communities are open to colonization because (1) interactions are not limiting richness, (2) the colonizing species uses niche space that is not occupied by the *in situ* residents, or (3) after contact with the residents, evolution of niche partitioning occurs. In association by colonization, the community is rich or poor because its region has high or low barriers to colonization from elsewhere. It is likely that real communities are mixtures of colonists and *in situ* descendants,

and Brooks and McLennan have pioneered the development of phylogenetic methods to distinguish between these two groups.

The influence of higher colonization rates into a region on regional and thus local richness is obvious, but the role of history is less so. Why are some regions historically richer than others? The answer to this question must involve region-specific differences in historical speciation rates, extinction rates, or both. Some processes might act to increase the speciation rate relative to the extinction rate. For example, some taxa may have developed key innovations that allowed them to enter a new adaptive zone and undergo an adaptive radiation. The region may have been simultaneously dissected by colonization barriers, disrupting gene flow among many populations and resulting in a burst of speciation.

Latham and Ricklefs present a possible example in the evolution of frost tolerance and proliferation into the temperate zone by forest trees. Asian temperate forests have three times more tree species than North American forests and six times more than European forests. Because Asia may be particularly diverse topographically and has no geographic barrier between the tropical and temperate zones, such proliferation may have occurred more frequently than in North America and Europe, where such barriers do exist (Ricklefs and Schluter, 1993). Alternatively, some taxa may undergo non-adaptive bursts of speciation resulting from inherent biological attributes, including genetic peculiarities (e.g., chromosomal anomalies or polyploidy), mate recognition and selection, or other factors. A dramatic example is the anomalous diversity of the Hawaiian *Drosophila*. The proliferation of this genus in Hawaii far exceeds that in any other

Figure 2 Phylogenetic and biogeographical patterns that suggest association by descent. Species sets (2, 7, 12) and (3, 6, 13) comprise communities that were found on opposite sides of a geographic barrier. The phylogeny (A) indicates that species sets (2, 3), (7, 8), and (12, 13) each had a common ancestor. These two patterns suggest that both communities descended from a common ancestral community that existed before the barrier was formed. (B) The species in each extant community are thus associated because their ancestors were associated. Reproduced from Brooks and McLennan, in Ricklefs RE and Schluter D (eds.) (1993) *Species Diversity in Ecological Communities: Historical and Geographical Perspectives*. Chicago: University of Chicago Press.

region of equivalent area and has been attributed to a strong tendency for sexual selection in the Hawaiian taxa (see Cornell and Lawton, 1992). Adaptive and nonadaptive radiations might be distinguishable by differences in the relationship between speciation rate and richness. In adaptive radiation, speciation rate should at first exceed extinction rates and then come into balance with extinction as regional richness increases and the adaptive zone fills up. Nonadaptive radiations do not require ecological diversification, and thus speciation and extinction rates should be unaffected by regional richness. Adaptive and nonadaptive radiations are not mutually exclusive and both could be operating in the same clade.

Other processes might act to increase extinction rates relative to speciation rates in some regions. Increased probability of extinction is believed to be linked to low average population size, which in turn is correlated with geographic distribution. Thus any event that reduces a species' range, such as habitat destruction or displacement by an invader, is likely to decrease its time to extinction. Returning to temperate forest trees, glaciation in conjunction with mountain barriers in southern Europe might have squeezed the geographic ranges of many temperate tree species below a critical threshold, driving them to extinction. The absence of mountain barriers in Asia and North America may have allowed temperate species to survive in southern refuges, accounting in part for the higher tree species richness in those regions.

The relative importance of colonization, speciation, and extinction rates in setting regional richness will vary depending on the taxon and the history of the region. Since regional and local richness are linked, an understanding of community assembly will require a new focus on these macroevolutionary processes. Fortunately, new phylogenetic methods involving sister group comparisons and other innovations have been developed by Mitter, Farrell, and others, which can distinguish among various macroevolutionary causes for regional and local richness variation. Such methods have given history and biogeography the consideration they deserve in some modern investigations of community structure (e.g., McPeck and Brown, 2000), but more work needs to be done. Community structure is undoubtedly influenced by contemporaneous processes as well, and distinguishing historical from present-day effects such as energy, local environment, and species interactions will be one of the biggest future challenges in this area.

Metacommunity Processes

Once species become part of the biota of a particular region, they can disperse among habitats, and as a result communities can be quite dynamic in space and time. The species within the region can thus be viewed as a species pool for a given local habitat. The species pool will be considerably larger than the number of species in any habitat for at least three reasons: (1) some species in the region will not be able to disperse to all sites because of colonization barriers or isolation-by-distance; (2) all habitats in the region are not favorable for all species; and (3) species can be driven locally extinct by species interactions, demographic and environmental stochasticity, disturbances, or other unfavorable changes in

local conditions. It is of some interest to explore situations where species cut off by highly effective colonization barriers are not considered part of the pool for habitats from which they are isolated. The dynamic links between local and regional richness should thus be examined at a spatial scale where all species can reach all habitats over ecological time. Moreover, we should focus on a single habitat type, since looking at more than one habitat will confound regional effects with local environmental variation. This can generate artifactual relationships between local and regional richness (Srivastava, 1999). The metacommunity within the landscape, in its simplest form, fulfills both of these criteria and thus represents an appropriate theoretical context in which to examine these links. The term metacommunity was first used by Gilpin and Hanski in 1991. The metacommunity can be thought of as a pool of species in a fragmented landscape of environmentally identical sites, each species behaving as a metapopulation in that its distribution among sites in the landscape is determined by colonization and extinction. In this scenario, regional processes still determine the potential species pool, but now the effects of the pool on local richness are filtered through the metacommunity.

The simplest metacommunity model derives from Richard Levins' original 1969 equation for a single-species metapopulation:

$$\frac{dp_i}{dt} = c_i p_i (1 - p_i) - m_i p_i$$

Tilman and Lehman used this equation to construct a metacommunity model by writing independent equations for as many species as occur in the metacommunity (Tilman and Kareiva, 1997). The value of p_i is the proportion of local sites in the landscape occupied by the i th species, and c_i and m_i are the site-specific colonization and extinction rates, respectively. Thus, when $dp_i/dt = 0$, each p_i is set by a balance between colonization and extinction rates per site. The model assumes that all sites are identical. This assumption permits the examination of links between local richness and pool size without the confounding effects of local environmental variation. If p is defined as the mean of p_i 's for all species, then p becomes the average proportion of local sites occupied by a species. Alternatively, it is the average proportion of the metacommunity found at a particular site. Thus, local richness = p (landscape richness).

What this expression tells us is that if p is a constant then local richness is a linear function of landscape richness, a pattern that has been called Type I or proportional sampling (Figure 3). Proportional sampling predicts that matched habitats embedded in richer landscapes will always have richer communities, but that local richness will be less than landscape richness by a constant proportion. The slope of the relationship, p , will be determined by the size of the pool balanced by the rate of species extinction at individual sites. In this simple model, species-specific colonization and extinction rates are assumed to be independent of pool size and the number of species at a site. Thus the model predicts the relationship between local and landscape richness in the absence of species interactions. Under these conditions, communities will be unsaturated and open to colonization from the species pool.

Figure 3 The shape of the relationship between local and regional richness in Type I and Type II communities. The linear relationship in Type I communities suggests that they are strongly influenced by the size of the regional species pool. Type II communities are asymptotic, suggesting that they are saturated and that further increases in the regional pool will not affect local richness. Real communities can also occupy the gray zone. Reproduced from Cornell HV and Lawton JH (1992) Species interactions, local and regional processes, and the limits to richness in ecological communities. *J. Animal Ecol.* 61: 1.

At least one recent study by [Hugueny and Cornell \(2000\)](#) has shown that the proportional sampling pattern in a real species assemblage can be predicted from colonization and extinction rates. Metacommunity models can be made more realistic by adding rescue effects, by adding provisions for variable population sizes among patches, by making habitats differentially suitable to different species, and by incorporating source-sink effects and habitat specialization. Such modifications may alter the details of the Type I curve, but they will not alter the conclusion that pool effects strongly influence community richness. Thus, for the purposes of conceptual distinction between saturated and unsaturated communities, the Levins model suffices.

The Levins model not only predicts the relationship between landscape and local richness; it also shows that the landscape filter constrains the species pool. Most obviously, landscapes that are smaller will have smaller species pools as predicted by the species–area relationship. More subtly, landscapes of a given area that are more highly fragmented will have smaller species pools because they suffer higher landscape-scale extinction rates. Fragmentation also reduces the average proportion of the pool (p) found at a local site by lowering per site colonization rates and increasing per site extinction. Thus any differences in landscape characteristics must be considered when estimating the species pool and evaluating the proportional sampling relationship.

If competitive interactions are added to the model, and it is assumed that competition leads to extinction rather than character displacement and speciation, then increased competition can result in increased extinction rates and/or decreased colonization rates per species. As the species pool increases, competition could become sufficiently intense that colonization by a new species into the community would either fail or result in the rapid extinction of other species. Under this condition, further increases in the pool do not

result in increases in local richness and the community becomes saturated with species. At saturation, the relationship between local and landscape richness levels off and becomes independent of the rate of colonization and the size of the species pool. This leveling relationship has been designated Type II ([Cornell and Lawton, 1992](#)). Species interactions are thus limiting local richness consistent with the Volterra–Gause perspective. Other dynamic models developed by Caswell and Cohen (in [Ricklefs and Schluter, 1993](#)) and [Morton and Law \(1997\)](#), which allow for dispersal, species interactions, and local extinction, also predict leveling off and saturation.

However, the spatial character of many dynamic models allows for realistic complexities that ameliorate the impact of species interactions on local richness. For example, if competition occurs only among close neighbors, and inferior competitors are better dispersers, then a potentially unlimited number of species can coexist locally ([Lehman and Tilman, in Tilman and Kareiva, 1997](#)). Other spatial models incorporating disturbance, limited dispersal, spatially local competition, and habitat heterogeneity also predict coexistence at high levels of richness in the face of competitive interactions ([Cornell and Karlson, and Lehman and Tilman, in Tilman and Kareiva, 1997](#)). Thus Type I relationships can still occur in the presence of intense competition.

It is important to point out that just because metacommunity and other models predict proportional sampling or saturation under certain conditions, it does not mean that the Type I or Type II relationships need be explained exclusively by mechanisms operating at the landscape scale. The models simply represent theoretically plausible ways in which the pattern can be generated. Factors operating at other spatial scales can also produce Type I and Type II relationships. For example, suppose the scale of the analysis is expanded to the entire region. One reason to do this is that regions are easier to define than landscapes and thus more data on regional richness have been collected. Type I and Type II relationships are thus more conventionally represented as plots between local and regional richness (see [Figure 3](#)). Under these circumstances, Type I relationships can result simply from dispersal limitation. That is, when regions of different species richness are compared, a constant proportion of the regional biota is unable to reach the habitat type of interest. Type II relationships, on the other hand, can be generated by historically stable communities in which all niche space is occupied and into which invasion is limited. In such situations, the community need not be particularly dynamic, need undergo little turnover in ecological time, and its species composition may bear the strong stamp of its historical development. Nevertheless, a Type I relationship would still be an indication that hard limits on local richness have not been reached even in the richest regions, whereas a Type II relationship would suggest saturation. The Type I and Type II relationships should thus be viewed as empirical patterns with multiple causes, but also as evidence that local richness is or is not limited by local factors.

Testing for Saturated Communities

The Method

The preceding theoretical exploration suggests that one can test for saturation by examining the relationship between local

richness and some reasonable estimator of the species pool. Regional richness has been the most commonly used estimator for the reasons stated earlier. To test for saturation, matched habitats are compared in different geographical regions of similar size that support different numbers of species. Habitats in richer regions are presumably exposed to richer species pools. Choosing regions of similar size should reduce any differential effects of colonization barriers that might generate differential dispersal limitation among regions (see Cornell and Lawton, 1992; Caley and Schluter, 1997). If the communities are unsaturated, local richness should increase steadily with increases in regional richness. The shape of the relationship can be linear (Type I) or curvilinear, but it cannot level off. Curvilinearity would suggest some resistance to invasion and thus a tendency toward saturation in richer regions, but that the limit to local richness has not been reached. If communities in the richest regions are saturated, then the curve will reach an asymptote and local richness becomes independent of regional richness (Type II).

The method assumes that matched habitats and species in different regions are similar in ways that are critical to species coexistence. This means that if there is the potential for saturation at some level of local richness determined by local environmental conditions and the characteristics of individual species, that level will be the same from region to region. However, even if matched habitats are environmentally identical, some communities might exhibit multiple stable points and saturate at different levels, for example, due to differences in colonization order as shown by Drake. If the community is near saturation, multiple stable points might increase the variance around the putative asymptote but should not affect the average tendency for local richness to level off.

The Tests

Two recent surveys by Cornell and Karlson (1997) and Srivastava (1999) have evaluated the frequency of Type I and Type II relationships in a variety of species assemblages. The surveys were combined by Lawton (1999) to yield 38 papers. Some of the data were not analyzed strictly according to the protocol presented here, and in these cases interpretation of the pattern was conservative and based on common sense. By conservative estimate, there were at least 23 examples of Type I relationships (wood-boring beetles, tiger beetles, fig wasps, lizards, corals, plants, helminth parasites on introduced fishes, 6 examples of fish, 4 examples of plant-feeding insects, 3 examples of parasitoids, 2 examples of birds, and a variety of vertebrate taxa (birds, fish, mammals, reptiles) analyzed separately and in combination). By contrast, there were 15 examples of curvilinear relationships, and not all of these were Type II (saturating). The examples are classified as saturating (strong), weakly curved (weak), or uncertain (u) as follows: marine crustaceans (u), deep-sea gastropods (weak), tiger beetles (u), 2 examples of helminth parasites on fish (strong), helminth parasites on amphibians (strong), 2 examples of fish (u), 2 examples of birds (weak), 2 examples of mammals (strong), and 3 examples of higher plants (1 strong, 2 weak).

Caveats

Several methodological concerns about the saturation test have been raised by various authors. The most relevant of these to the present discussion are that various artifacts such as nonhomogeneous variance structures, insufficient sampling, and overestimates of the true species pool in richer regions sometimes exaggerate the curvilinearity of the relationship between local and regional richness. To the extent that such artifacts are present in some studies, true Type I relationships might appear curvilinear, and curvilinear but unsaturated relationships might appear to be Type II. The count of unsaturated patterns in the survey is thus a conservative and robust result, at least with respect to the presence of such artifacts.

Saturated or Unsaturated?

Given these caveats, at least it can be said that unsaturated patterns are common and widespread in ecological communities. Indeed, unsaturated patterns have been reported about twice as frequently as saturated ones. The survey thus confirms that local communities are often open to regional influences and have not reached any upper limit set by species interactions as predicted by the Volterra–Gause model. Those communities that have reached an asymptote might be saturated but have to be examined closely to rule out artifacts that might be responsible for the Type II shape. A Type II curve is not sufficient in and of itself to conclude that species interactions are limiting local richness. For example, helminth parasite communities on fish and amphibians appear to be saturated, but at least one expert opinion is that they are probably not (see Lawton, 1999).

The survey also supports the theoretical position that strong interspecific interactions are not always sufficient to generate a curvilinear or Type II relationship. Taxa that are known to experience strong interspecific interactions such as fish and birds show Type I or weakly curvilinear relationships that are characteristic of unsaturated communities. Although it is not certain that these particular assemblages were experiencing the strong interactions that are supposedly characteristic of these taxa, the results at least suggest that evidence for species interactions by itself might not permit generalizations about the effects of these interactions on broad patterns of community structure.

Experimental Support

Additional evidence from experimental introductions supports the survey results that communities are often unsaturated. Experimental manipulations of the species pool are only just beginning, but they are particularly useful because there is better control of confounding variables. In separate studies by Tilman (1997) and Robinson, Quinn, and Stanton (1995), seeds of native species were added to experimental plots containing different numbers of plant species and establishment was monitored. In the Robinson *et al.* study, California poppy was the test colonizer, and in the Tilman study, anywhere from 0 to 54 species were added to plots. Neither study showed evidence of saturation; seeds became

established and persisted in many plots. Unsaturation was dramatic in the Tilman study, as the number of species in the experimental plots continued to increase over the full range of species additions and the increases persisted for 4 years (Figure 4). In other words, an asymptote characteristic of the Type II relationship was never reached. However, plots that were richer in resident species had lower establishment rates, suggesting some resistance to invasion.

The results of these experiments must be interpreted with caution, as they represent short-term responses to pulsed increases in the species pool. There are almost certainly time lags in the response of the community to species additions, and long-term monitoring will be required to confirm that the “invaders” have become established without driving “residents” extinct over ecological time. Nevertheless, pool manipulations offer a powerful probe for saturation and need to be expanded to other taxa and habitats to test the generality of these results.

Matters of Spatial Scale

A central issue in the exploration of saturation in communities is the spatial scale at which local richness should be measured.

Ideally, a locality should be ecologically defined. That is, a scale should be chosen within which all species of interest are interspersed and can potentially interact and within which the local environment is homogeneous. Since different species interact at different scales, and environments that are homogeneous for one species may be heterogeneous for others, the ideal locality will probably have indistinct boundaries. It may circumscribe the number of herbivore species associated with a host plant species, the number of insectivorous birds found in a patch of woods, or the number of flowering plant species associated with a serpentine outcrop. Local samples must be standardized in some way so that they are comparable among regions. Typically, the number of individuals or the unit area assessed is uniform, or local assemblages are sampled until the species/sampling curve levels off.

If regional richness is sufficiently high to engender saturation, it is not patently clear at which scale it should occur. Communities are hierarchically structured assemblages of organisms that may be saturated at one scale and not other scales because the intensity of dynamic coupling among species varies with the unit of study. Most comparisons of local and regional richness offer few clues about the relationship between hierarchical structure and saturation because local

Figure 4 Species richness of vascular plants in 0.25-m² prairie plots (1-m² plots in 1995) after the experimental addition of seeds in 1992. Seed additions ranged from 0 to 54 species and the plots were followed for 4 years (1992–1995). The 0 species addition (data on the Y-axis) shows changes in species richness in plots not subject to manipulation. Species richness increased steadily over the entire range of species additions and the increases persisted for at least 4 years. The results suggest that these plant communities are highly recruitment limited and not saturated with species. Reproduced from Tilman D (1997) Community invasibility, recruitment limitation, and grassland biodiversity. *Ecology* 78: 81.

richness is evaluated at only one scale. Clearly, a more methodological exploration of hierarchical structure that involves multiscale sampling is required. A few studies have made limited attempts at a multi-scale analysis. Caley and Schluter (1997) measured local richness from distributional data of 10 different taxa at two local scales (1% and 10% of regional area) in various regions. All taxa fell along a Type I trajectory at both scales (Figure 5). In a 1996 paper Kennedy and Guégan showed that parasite communities reached a hard upper limit of four species in individual eels whereas parasite richness in the eel population as a whole continued to increase steadily with regional richness. Finally, data on coral assemblages examined by Karlson and Cornell (2002) showed that local richness was less sensitive to regional richness in 1-m²

quadrats than in 10-m line transects. In the latter example, the 1-m² quadrat is so small relative to the size of some coral colonies that local richness, particularly in very rich regions, could be limited simply by the number of individuals that can be packed into this small sample. In all three examples, only two local scales were examined, but for two of these examples, this was sufficient to show differential responses of local richness to changes in regional richness. Clearly, multiscale analyses will permit stronger inferences regarding saturation, or lack thereof, in communities. They will also be useful in defining the spatial arena within which local processes, which might in some cases limit local richness, should be sought.

Synthesis of Community and Regional Perspectives

A Thought Experiment

Since processes operating at scales larger than the local habitat (e.g., landscape or region) almost surely affect local richness, research emphasis must shift to these larger-scale processes. Only then can patterns of community assembly be completely understood. However, this shift does not imply that local processes should be ignored. Local- and larger-scale processes may both affect local richness and their relative influence must be determined. The advantages of this multi-scale perspective can be illustrated with a thought experiment. Suppose we have two climatically similar regions with different regional richness due to historical factors. The Asian and European temperate forests discussed previously provide a good example. Suppose further that physically identical habitats of two types (e.g., sandy versus loamy soils) were transplanted into these regions and were allowed to achieve a steady state that showed no influence of initial colonization history. Once the steady state was reached, by how much would per locality tree species richness vary among habitat types and regions? The transplanted habitats would make it possible to partition the contribution to per locality richness among processes operating at local and regional spatial scales. The design would also make it possible to evaluate interactions between regional and local factors and to examine mediation of species interactions by changes in the local environment.

Manipulations of Productivity and the Pool

Although the preceding experiment is possible in principle, it is likely to be difficult to carry out. Also, it is difficult to be sure that climatic conditions that may affect local processes are truly identical among regions. An alternative to habitat transplantation is a two-factorial manipulation of the species pool and local environmental conditions in the same region. For example, suppose some high-productivity lakes in a particular region had unusually low fish species richness. Is the low richness due to interaction mediation or pool limitation? Manipulations could be designed in which the entire fish species pool could be added to lakes of different productivity. In addition, productivity itself could be manipulated by adding fertilizer to particular lakes. Care would have to be taken that the fish were adapted to live at the prevailing productivity levels. A full two-factorial design would make it possible

Figure 5 Local versus regional richness relationships at two local scales (1% and 10% of regional area) for 23 different taxa that have been combined for this analysis. The relationship is Type I at both scales, with the main difference being that the slope of the curve is roughly 10% lower at the smaller scale, consistent with the species-area relationship. The size of the locality has no effect on the tendency for saturation over this range of spatial scales. Reproduced from Caley MJ and Schluter D (1997) The relationship between local and regional diversity. *Ecology* 78: 70.

Figure 6 Hypothetical changes in communities over time showing that differences in the community due to habitat characteristics can be used to estimate community convergence. The community character in this case is species richness. (A) X indicates the richness value toward which the community will converge because of habitat characteristics. Open circles represent some unusually rich ancestral state of the communities in both habitats because, for example, they are located in a rich region and have been subject to a massive colonization event. Solid circles represent an alternative, depauperate ancestral state, because, for example, the communities are located in a species-poor region and have been subject to a disturbance. (B) Over time, communities will converge on X and the variance components due to habitat and region can be used to estimate the relative contribution of habitat and regional effects on local richness. (C) A slightly different case, but the inferences are the same. Reproduced from Schluter D (1986) Tests for similarity and convergence of finch communities. *Ecology* 67: 1073.

to sort out pool effects, productivity effects, and pool X productivity interactions on local richness (see Two Perspectives on the Control of Community/Regional Diversity). If regional control of community structure is important, then pool effects or pool X productivity interactions should have important effects on local richness.

A Comparative Approach

In situations where experiments are intractable or when it is desirable to examine longer-term effects, the problem can be addressed using a statistical comparative approach. For example, Schluter and Ricklefs (in Ricklefs and Schluter, 1993) have suggested using multi factorial methods to partition the variance in local richness into components that can be explained by habitat differences within regions and species richness differences among regions. To the extent that local environments constrain local richness, species richness in similar habitats from different regions should converge relative to some hypothetical ancestral state of the community (Figure 6). Detecting convergence is thus equivalent to measuring the variance component due to habitat differences. Important regional effects on local richness will be detectable in the variance component due to differences in regional richness. Schluter and Ricklefs calculated variance components for 36 different studies and found strong convergence in many cases, consistent with significant local effects on local richness. Yet there were strong regional differences in richness within similar habitats as well. Using regression methods to study coral reef communities, Karlson and Cornell (1998) similarly found both local and regional effects to be important.

Conclusions

The results from experimental and statistical analyses confirm that both local and regional processes have important effects

on local richness. Thus, not only must experimental work on local communities be continued, but investigations need to be expanded to encompass larger-scale processes as well. The Volterra–Gause image of an ecological system at equilibrium and independent of historical processes has undeniable appeal, and has engendered much productive research on community assembly. Nevertheless, integration of historical, biogeographical, and metacommunity processes with local interactions and environmental variation is essential for a complete understanding of richness variation in species assemblages.

Glossary

Biotope Region that is distinguished by particular environmental conditions (climate, soil, altitude, etc.) and therefore a characteristic assemblage of organisms.

Stenotopic Referring to taxa with restricted habitat requirements (i.e., confined to a single biotope) and hence restricted distributions.

Endemic taxa are those restricted to a specified geographical area. Therefore, the concept is a relative one; the patterns, correlates, and causes of endemism will vary according to the size and location of the geographical area, as well as the taxonomy and phylogenetic relatedness of the assemblage under consideration. At a global scale, all taxa are endemic and there is relatively little to say on the topic. Most research has focused on species that are endemic to relatively small areas. In this sense, endemism is best viewed as a form of rarity, that is, range-restricted rarity. This article presents biogeographical, evolutionary, ecological, and conservation perspectives on endemism and discusses generalizations regarding the patterns, correlates, and causes of species-level endemism in relatively small areas.

Categories

Endemics may be categorized according to their spatial distribution, inferred evolutionary age, affinities, and local abundance.

Spatial Distribution

Endemics are loosely and commonly categorized in four contexts of spatial distribution: site or restricted area; biotope; biogeographical region; and political area.

Evolutionary Age and Affinity

Categorization of endemics according to evolutionary age and affinity is summarized in **Box 1**. These schemes have been widely used by botanists but rarely by zoologists. Problems associated with the schemes are that (1) age is regarded as a categorical rather than continuous variable; (2) the establishment of relationships among taxa lacks rigor; and (3) many palaeoendemics are diploid.

Phylogenetic methods, which consider the distribution of characters among taxa in a cladistic context, provide a rigorous categorization of endemics in terms of relative age and propinquity of descent. In this context, low-ranking taxa correspond to neoendemics and high-ranking taxa to palaeoendemics (cf. **Box 1**). An absolute estimate of the age of endemics can be given when congruent phylogenetic relationships correlate with identifiable historical events.

Local Abundance

The classical, biogeographical perspective on endemism has tended not to consider the local abundance of species. However, in the more recently developed ecological and conservation perspectives, in which endemism is conceived as a category of rarity, population abundance is invariably explicitly considered. Thus, geographical range size as a categorical variable (wide/narrow) has been used as one of the

Box 1 Categorization of endemics according to evolutionary age and affinities

A. Engler's scheme, published in 1882.

1. Neoendemics: comprising clusters of closely related species and subspecies that have evolved relatively recently.
2. Palaeoendemics: comprising phylogenetically high-ranking taxa, usually monotypic sections, subgenera, or genera that may be regarded as evolutionary relicts.

R. C. Favarger and J. Constandriopoulos's scheme, published in 1961. This scheme uses cytological data to provide a more rigorous basis for assessing the age and affinities of endemics.

1. Palaeoendemics: ancient isolated taxa with a high ploidy level, whose diploid ancestors are extinct or unknown.
2. Schizoendemics: vicariant species of equal ploidy level, resulting from either gradual or rapid divergence.
3. Patroendemics: restricted diploid species that have spawned younger, widespread polyploid species.
4. Apoendemics: polyploid endemics that are derived from widespread species of a lower ploidy level.

Schizo-, patro-, and apoendemics are further subdivisions of Engler's neoendemics.

factors in defining seven forms of rarity recognized for plants. Endemics (narrow range) may belong to any four categories of rarity according to biotope specificity (broad/restricted) and local population size (somewhere large/everywhere small).

Perspectives

The concept of endemism has a long history in biology, dating back to A. P. De Candolle's treatise, published in 1820. Most research on the topic has been in the field of descriptive biogeography, where distribution patterns of taxa have been used to define centers of endemism at various spatial scales. This approach provides a static perspective of endemism.

Over the past few decades, historical biogeographers have evaluated areas of endemism for monophyletic lineages in a phylogenetic context. This approach provides a dynamic perspective of endemism, especially when endemic taxa show congruent phylogenetic relationships that can be correlated with historical events.

Evolutionary biologists, studying both fossil and extant biotas, have explored the role of range restriction as a cause and consequence of speciation. Recently, several statistical techniques have been employed—collectively termed the comparative method—to exploit the phylogenetic relationships among species to extract independent information on the evolutionary correlates of endemism. These techniques acknowledge that related species may have similar range sizes, that is, range size cannot be assumed to be independent among species. However, in at least some cases, variance in range sizes seems to be partitioned mostly at the species level.

Community ecologists have conceptualized endemism as one of several forms of rarity, namely, range-restricted rarity, and have explored its role as an explanatory variable for taxon-specific ecological traits, such as local population size, body size, reproductive fitness, and dispersal distance. Increasingly, they are using comparative methods to correct for phylogenetic relatedness among biotas. However, for every cause–effect relationship documented, there are numerous exceptions.

Conservation biologists view range-restricted rarity as an attribute that predisposes a taxon to extinction. They seek to understand the abiotic and biotic correlates of this form of rarity as a basis for management guidelines that will reduce rates of extinction. A distinction is often, although not always, made between naturally rare species that may have some adaptation to rarity and those that have previously been widespread and are now restricted. Conservation planners often use patterns of endemism to identify reserve systems that are representative of a region's biodiversity. Many reserve selection algorithms have been formulated to select sites that have a unique or endemic complement of species.

Measurement

In quantifying patterns of endemism, the units of measurement (spatial scale and taxonomic entity), the mode of reporting of the data (percentages or counts), and a number of biases all influence the interpretation of the results. Of great

importance is the relative nature of endemism: evaluation is always dependent on the spatial context and biological assemblage under consideration. This section provides a clarification of the problems and approaches associated with the measurement of endemism.

Units of Measurement

A variety of methods have been used to measure the range sizes of taxa. A useful distinction can be made between measures that attempt to estimate the extent of occurrence of a taxon—the distance between the outermost limits of a species' occurrence—and the area of occupancy—the area over which the species is actually found. The latter measure is particularly relevant for ecological studies that seek correlations between range size and environmental tolerances, as well as for conservation planning research; extent of occurrence is widely used in biogeographic studies.

Measures of endemism invariably seek to identify a subset of taxa within an assemblage that can be classified as having a lower than average range size. Within the biotas of larger-scale regions—biogeographic areas or countries—many researchers have recognized "local" endemics as a distinct category. However, the range size, or extent of occurrence, for defining this category is often arbitrarily set, varying between 50,000 km² (for Neotropical birds and plants, as well as for birds globally) to 2000 km² or less (for plants in the Cape Floristic Region). Endemics with extremely small range sizes—<5 km²—are regarded as point endemics. An approach that is increasingly being used is to evaluate endemism as a continuous variable, calculated as the sum of the inverse range sizes of all taxa in each quadrat (cell grid or map unit).

From both the biogeographical and ecological perspectives, patterns of endemism are best studied in relation to ecologically homogeneous, biogeographical regions. However, conservation planners often use political regions or property boundaries when evaluating endemism, since these may be the most effective decision-making unit for the preservation of endemics.

The taxonomic or phylogenetic scales employed also influence patterns of endemism. Centers of endemism identified on the basis of patterns among low-ranking taxa (sub-species or closely related species) often differ from those where the units are high-ranking members of the same lineage. Similarly, the spatial scale for defining endemism will vary among different taxa of the same rank.

Percentage versus Counts

Endemism may be expressed as a percentage of all extant taxa present, or as the absolute number of endemics in an area. Depicting plant endemics in biogeographic regions as percentages or counts, and using area and latitude as explanatory variables, results in different patterns with different significance (Figure 1). Some species-poor areas, such as oceanic islands and arid regions, although low in actual numbers of endemics, may support a high percentage of endemic taxa. Other areas, such as Madagascar, the Cape Floristic Region, and parts of the Neotropics combine high richness and high endemism for some taxa. Ideally, both measures

Figure 1 Relationships (Spearman's rank correlation) between two measures of endemism (percentages and counts) and area and latitude for plants in 52 biogeographical units in tropical and subtropical forests and savanna (●), temperate forest and woodland (○), Mediterranean-climate shrubland and woodland (▲), warm desert and steppe (■), cold desert and steppe (□), and boreal forest and tundra (▽) on continental landmasses across the globe. Reprinted from Cowling RM and Samways MJ (1995) Endemism and biodiversity. In: Heywood VH (ed.) *Global Biodiversity Assessment*, pp. 174–191. Cambridge, United Kingdom: Cambridge University Press.

of endemism should be considered when explaining patterns, but seldom are.

Biases

Endemism is influenced by taxonomic interpretation, sampling error, and human perceptions of rarity. Of particular importance is the fact that limited geographical exploration, as well as variation in the application of taxonomic concepts, introduces biases in the identification of endemics and the significance of their status. Pseudoendemics are widespread species incorrectly classified as endemics, whereas non-apparent endemics are endemic species that are incorrectly classified as widespread. The fact that widespread species are usually more thoroughly researched than those with smaller range sizes introduces biases in studies that explore the correlates of range size.

Patterns

There are very clear global and regional patterns of endemism for a wide range of taxa: endemics are not randomly distributed across the globe. However, these patterns are constrained by poor taxonomic knowledge and distributional data in key areas (e.g., the tropics) and for some taxa (e.g., most invertebrate groups).

Latitudinal Gradients

The incidence of endemism for whole assemblages in biogeographic zones increases with decreasing latitude (see Figure 1). Range sizes, as measured by latitudinal extent, increase for a wide range of organisms above a latitude of approximately 40°–50° N, but the same patterns are not evident in the Southern Hemisphere. There are many patterns that are not consistent with the generalization—termed Rapoport's Rule—that range sizes of taxa

decrease with decreasing latitude, as a consequence of greater ecological specialization in less seasonal environments. For example, very high endemism for terrestrial taxa is recorded in the mid-latitudes of the Southern Hemisphere, particularly in and adjacent to Mediterranean-climate regions. Marine teleost fishes have smaller range sizes at higher than at lower latitudes, and endemism for marine algae peaks in mid-latitude areas. These patterns are probably more a product of speciation and extinction processes than contemporary ecological conditions. Thus, widespread glaciation during the Pleistocene at high latitudes in the Northern Hemisphere resulted in the extinction of less tolerant terrestrial taxa. In mid-latitude Mediterranean-climate regions that escaped glaciation, rates of speciation, at least for plants, have overwhelmed extinction rates, resulting in an accumulation of habitat-specialist, range-restricted species.

Centers

Many centers of endemism—areas of higher than average concentrations of range-restricted taxa—have been recognized globally and regionally, principally for higher plants and large-bodied terrestrial vertebrate faunas. Generally, many groups of organisms show a concentration of centers at lower latitudes (Figure 2). Following from the previous section, it is no surprise that the high-latitude areas of the Northern Hemisphere support few centers. However, this is not always the case in the Southern Hemisphere, where large numbers of range-restricted taxa occur in middle- to high-latitude land-masses that were never glaciated during the Pleistocene.

Congruence

Overlapping or congruent areas of endemism for different taxa have been used extensively by biogeographers to reconstruct

historical events. Patterns of congruence of endemism are also important for identifying reserve systems that maximize the preservation of different biotas.

Although strong patterns of congruence have been recognized for some taxa at the global scale—for example, swallowtail butterflies and tiger beetles, amphibians, birds, and mammals—higher plant centers often do not coincide with faunal centers. Nonetheless, on the basis of congruent patterns of endemic species diversity for mammals, reptiles, amphibians, and higher plants, it has been possible to identify 17 “megadiversity countries” (Table 1), that is, political units of high conservation value.

At a finer scale, patterns are highly variable among different taxa and in different regions, and no generalizations have emerged. This lack of strong congruence underlines the fact that endemism is an expression of many different causes, both ecological and historical.

Correlates and Causes

Range size or degree of endemism shows some clear relationships with a wide array of abiotic and biotic factors. These correlations are very useful in conservation biology since they may be used to identify factors that predispose endemic species to extinction. However, correlates may be either a cause or a consequence of endemism. To identify the causes of endemism in an evolutionary context, comparative methods that exploit phylogenetic relationships must be employed.

The causes of endemism are complex and numerous, and include intolerance of widespread habitats, niche specialization, isolation in marginal habitats owing to climate change, phylogenetic predisposition to narrow habitat selection, competition from alien species, and recent speciation of

Figure 2 The distribution of Endemic Bird Areas of the globe, as recognized by Birdlife International. These centers are identified on the basis of the distributions of 2609 bird species that have had in historical times a global breeding range of less than 50,000 km². isolates in marginal habitats. Therefore, historical processes, contemporary ecological factors, and inherent biological properties of lineages are involved. In many cases, historical factors may be overriding, resulting in a poor relationship between measures of endemism and explanatory variables reflecting the contemporary environment.

Establishing correlates is a useful step in explaining patterns and causes of endemism. Most pertinent studies have addressed the following question: When compared to more widespread taxa, are endemics, however defined, a random subset of the biota with regard to abiotic and biotic factors? Developing these profiles, however, has been complicated by different definitions of endemism, multiple interactions between different traits, and a failure to consider phylogenetic relatedness. This section provides a brief review of the abiotic and biotic interspecific correlates of narrow range size, and concludes with an assessment of the role of endemism in speciation.

Regional Species Richness

There is often a positive relationship between the incidence of endemism and regional-scale richness. This results from the importance of high habitat-related and geographical compositional turnover (beta and gamma diversity, respectively) in producing regional richness. Habitat specialists (or stenotopic

species) and geographical vicariants often have narrow range sizes. However, there are also many cases where patterns of endemism and diversity are largely noncoincident. Examples include plants in the Neotropics, birds in the Andes, dragonflies and terrestrial vertebrates in southern Africa, and the biotas of many oceanic islands and deserts.

Area

As a generalization, proportionate and absolute measures of endemism increase with increasing area (see [Figure 1](#)), irrespective of the taxonomic level. However, the relationship between number of endemic species (counts) and area is not as tight as that for the more widely studied species–area relationship. This results from the lack of congruence between endemism and richness in many areas (e.g., arid lands and oceanic islands).

Abiotic Environmental Factors

Levels of endemism may vary in a predictable way along gradients of rainfall, temperature, productivity, and habitat heterogeneity. Models that accurately predict levels of endemism on the basis of easily measurable environmental variables have been used for the rapid identification of endemic-rich areas.

For higher plants, levels of endemism increase with increasing productivity, with increasing elevation (reflecting increased habitat heterogeneity and isolation in high-altitude areas), and with higher rainfall in low- and middle-latitude areas, although many exceptions to these patterns exist. In the Mediterranean-climate regions of the Cape and southwestern Australia, there is a negative relationship between local endemism and soil fertility. In the California Floristic Province, palaeoendemism is clustered in the wettest and driest areas, whereas neoendemism occurs in transitional rainfall areas where rates of speciation are highest. Similar patterns exist for Afrotropical birds and Neotropical butterflies. For a wide range of marine taxa, endemism is more pronounced in exposed and variable nearshore environments than in the more stable distant-shore habitats.

Biotope

Geographically isolated areas and biotopes, such as certain islands, mountain peaks, ancient lakes, caves, thermal vents, hot springs, vernal pools, the abyssal zone, and chemically imbalanced substrata, support a disproportionately high number of stenotopic endemics.

Most studies have focused on endemism on islands, mountains, and unusual substrata. Generally, larger continental islands such as Madagascar, New Caledonia, and New Zealand support the greatest number and proportion of endemic taxa, especially of higher plants. Elevational range explains the incidence of plant endemism on the Canary Islands and bird endemism in Indian Ocean archipelagos, suggesting the importance of topographical diversity. Continental islands are typically rich in palaeoendemism, whereas some taxa have undergone extensive and unusual adaptive radiation on oceanic islands such as the Canaries and Hawaii.

Mountains are also often rich in endemics, in both tropical and temperate regions, but not in recently glaciated, high-latitude areas of the Northern Hemisphere. Many desert inselbergs (granitic outcrops) act as mesic refugia that support endemics; this is particularly pronounced for plants in middle Asia. As on islands, endemism on mountains results from both historical (e.g., isolation) and ecological (e.g., heterogeneity) factors.

The restriction of endemic plant species to nutritionally imbalanced substrata, especially when these occur in an islandlike configuration, is widespread in Mediterranean-climate and humid tropical regions. These sites provide both a strong selective force for the evolution of neoendemism and a refuge from competition for palaeoendemism. The restriction of animal taxa to unusual substrata has not been studied in any detail, but is likely to be a response to habitat effects on vegetation structure rather than nutritional peculiarities *per se*.

Biology

Very few studies have addressed the relationships between restricted range size and biological factors such as body size, growth form, life-history traits, population size, and genetic architecture. Of these studies, few have considered multiple trait interactions or phylogenetic relatedness.

As a generalization, there is a positive, albeit weak relationship between a species' range size and its local population abundance for a wide range of taxa (Figure 3). However, not all endemics have low local abundances; indeed, many narrow plant endemics are extremely abundant locally. There are a number of hypotheses to explain the positive relationship between range size and local abundance. These are based principally on artefacts (e.g., sampling effects), resource use, metapopulation dynamics, and spatially independent rates of

Figure 3 Relationship between the maximum local abundance value for North American birds and the number of sites at which each was recorded. Reprinted from Gaston KJ (1994) *Rarity*. London: Chapman & Hall, with permission from Springer.

Figure 4 Relationship between the geographic range size ($\text{km}^2 \times 1000$) and the body mass (g) of Neotropical forest mammals. Reprinted from Gaston KJ (1994) *Rarity*. London: Chapman & Hall, with permission from Springer.

population growth. This pattern and its causes are currently attracting considerable attention.

There is a broad positive relationship between geographical range size and body size for animal species (Figure 4). There is also a trend, both within regional floras and specific taxa, for low-stature growth forms to be overrepresented among plant endemics. This is especially true of the South African Mediterranean-climate region, where low shrubs (Figure 5) dominate the endemic flora. Among Neotropical forest plants, endemics tend to be herbs, shrubs, or epiphytes rather than forest trees, whereas in the rain forests of Sri Lanka, endemics are overrepresented among long-lived, late-successional trees.

Gigantism is a common feature among some plant groups endemic to alpine habitats at low latitudes. Among animals, gigantism, dwarfism, and flightlessness are widespread among island endemics, as well as among some continental endemics associated with insular biotopes.

The reproductive correlates of endemism have been more extensively studied than other biological attributes. There are a number of pertinent generalizations, although exceptions exist for all of them. Range-restricted species differ from common ones in that they:

- tend to be self-compatible or rely on asexual reproduction;
- tend not to be wind-pollinated or have other inefficient forms of pollen transfer;
- invest less in reproduction;
- have poorer dispersal abilities;
- have shorter generation times.

The last two attributes are shown in Figure 5, where short-distance ant dispersal and fire sensitivity (rapid generation time) are overrepresented among plant endemics in a mountain region of the Cape Floristic Region in South Africa. However, these and other reproductive traits, such as seed size, seed number, and reproductive investment, all interact in complex ways. Furthermore, these traits are not independently distributed among species.

Many studies indicate that plant and animal endemics have lower levels of genetic variation in comparison with

Figure 5 Percentage of endemic and nonendemic species in the Langeberg mountain flora (Cape Floristic Region, South Africa) in (a) seven growth form classes (G = geophyte, HG = graminoid, FO = forb, T = tree, LSH = low shrub, MSH = mid high shrub, TSH = tall shrub); (b) two postfire regeneration classes; and (c) four dispersal mode classes. Chi-square analyses were performed on untransformed data. Reprinted from McDonald DJ and Cowling RM (1995) Towards a profile of an endemic mountain fynbos flora: Implications for conservation. *Biol. Conserv.* 72: 1–12.

widespread congeners. This may be due to several factors, including adaptations to narrow ecological conditions, small population size, and self-incompatibility in plants. However, there are also cases of little difference in genetic diversity between closely related endemic and widespread plant species.

Taxonomy and Phylogeny

Many biotas that are endemic to biogeographic regions are not a random phylogenetic assemblage. Some plant families are significantly overrepresented among the endemic floras in many parts of the globe, especially in Mediterranean-climate regions. The same is true of certain dragonfly families in southern Africa. Among plants, Cyperaceae and Poaceae are underrepresented as endemics in many floras throughout the world. In many cases, these patterns can be attributed to taxon-specific biological attributes that predispose a lineage to endemism. Thus, the existence of discernible phylogenetic correlates of endemism implies that range size may be an evolutionarily stable character of a lineage. Hence there is a need for the comparative approach to assess the role of phylogenetic relatedness in explaining patterns. However, it is important to establish the taxonomic level at which these relationships are manifested. For example, for several data sets, the majority of variation in range size is explained at the level of species within genera.

Endemism and Speciation

At face value, the relationship between range size and speciation appears to be quite simple: a reduction in range size will always accompany a speciation event, and a species nearing extinction—in an advanced stage of the taxon cycle—will occupy a limited range size. The deeper issue of the extent to which range size is a cause or consequence of speciation is a question of considerable interest.

There has been a long-standing and as yet unresolved debate regarding the causal relationship between range size and speciation. The arguments assume positive relationships between range size, population size, and dispersal ability. One viewpoint suggests that owing to extensive gene flow and reduced extinction rates, widespread taxa should have lower rates of speciation than range-restricted taxa. An alternative hypothesis is that owing to greater genetic variability and a higher frequency of founder effects, species that comprise large and well-dispersed populations that occupy large range sizes are prone to vicariant speciation.

Many studies of fossil and extant lineages suggest that turnover (speciation and extinction) is associated with relatively low local population abundance, poor dispersal, and narrow range size. Clearly, at extremely low values for these variables, extinction rates will overwhelm rates of speciation. Elevated speciation and extinction rates are also associated with increased specialization, reduced body size, and increased generation times; all of these are correlates of narrow endemism. Thus, endemism and its correlates are responsible not only for enhanced rates of speciation, but also rapid rates of extinction. In E. S. Vrba's parlance, these processes are flip sides of the same coin.

The alternative view, that speciation is associated with large, centrally located and wide-ranging populations, and that peripheral isolates are relictual taxa, also has support. Ultimately, aspects of this debate will be resolved by studies that assess range size and its correlates in a phylogenetic context.

Conservation

Because of their restricted geographical range size, high habitat specificity, and generally low population abundance, endemics are more vulnerable to extinction than are widespread and common species, as a result of both deterministic (habitat transformation) and stochastic (small population effects) factors. Therefore, considerable attention has been given to the conservation of local endemics. Attempts have been made to use the correlates of local endemism to devise management plans that will reduce anthropogenic extinctions.

Recent advances in systematic conservation planning have identified priorities for conservation on the basis of complementarity of biotas (representation), but also for the retention of biodiversity in the face of threatening processes. This approach involves the assessment of the irreplaceability of an area—a measure of the likelihood that the area will be needed to achieve a conservation goal—and its vulnerability to biodiversity loss as a result of current or impending threatening processes. Endemic-rich areas inevitably emerge as priorities since they combine high irreplaceability, owing to their unique biota, and high vulnerability, since endemics are prone to extinction. However, some endemics, particularly plants, may be preadapted to persist in small populations and could be effectively preserved in small, fragmented areas.

Conclusions

There are few generalizations regarding geographical patterns and correlations of endemism. This is understandable, given that definitions of endemism are mostly study-specific, and that endemism is partly a consequence of regional-specific historical events acting on phylogenetically distinct biotas. Furthermore, species with similar range size often have different local abundances that are likely to be manifested in very different biological attributes. Finally, within-region analyses invariably lump together palaeoendemics and neoendemics, groups with different origins and phylogenetic relationships, and often, different biologies. The recent trend to correct for phylogenetic relatedness holds much promise for understanding the ecological and evolutionary correlates of endemism.

The most active fields of research currently are studies on the correlates of range size, particularly local population abundance, body size, and reproductive traits; the role of endemism in reserve selection, especially as a measure of irreplaceability and surrogate measure of vulnerability; and historical reconstructions using congruent areas of endemism in phylogenetic studies. Much less classical biogeographic research is being carried out on the identification of centers of endemism, despite the fact that reliable distribution data are lacking for many areas and taxonomic groups. This lack of data has serious consequences for the identification of endemic-rich areas for conservation purposes.

Published by Elsevier Inc.

Glossary

Energy The capacity to perform work. Potential energy is this capacity stored as position (e.g., in a gravitational or electromagnetic field) or as structure (e.g., chemical or nuclear bonds). Kinetic energy is this capacity as manifested by the motion of matter. The joule (J) is the common SI unit of energy, where 1 J equals the amount of energy required to increase the temperature of 1 g of water by 1 K. Other units include kilocalories (kcal), kilowatt-hours (kWh), and British thermal units (BTU).

Energy efficiency A measure of the performance of an energy system. First Law efficiency, the most commonly used measure, equals the ratio of desired energy output to the energy input. Second Law efficiency equals the ratio of the heat or work usefully transferred by a system to the maximum possible heat or work usefully transferable by any system using the same energy input.

Energy, industrial Forms of energy generally transformed in bulk at centralized facilities by means of complex technology. The major forms of industrial energy are oil, coal, natural gas, nuclear, and hydroelectric. In addition to hydroelectric, industrial energy also includes other technologically complex renewable energy systems, including solar photovoltaics, wind turbines, geothermal systems, and biofuels.

Energy, nonrenewable Forms of energy whose transformation consumes the energy source. The major forms include oil, coal, natural gas, and nuclear.

Energy, renewable Forms of energy whose transformation does not consume the ultimate source of the energy,

harnessing instead solar radiation, wind, the motion of water, and subsurface water and geologic formations. The major forms of renewable energy are solar, wind, geothermal, hydropower, and biomass. Renewable energy systems that depend on complex technology are forms of industrial energy. The simpler renewable systems are forms of traditional energy.

Energy, traditional Forms of energy generally dispersed in nature, renewable, and utilized in small quantities by rural populations. The principal forms of traditional energy are firewood, charcoal, crop residues, dung, and small water and windmills.

Fossil fuels Forms of stored energy produced by the action of pressure and temperature on organic matter buried over geologic time. The major types of fossil fuels are oil, natural gas, and coal.

Law of Thermodynamics, First Physical principle that energy is neither created nor destroyed, only converted between different forms. Energy is therefore conserved. In thermodynamic terms, the change in energy of a system equals the difference of the heat absorbed by the system and the work performed by the system on its surroundings.

Law of Thermodynamics, Second Physical principle that any system will tend to change toward a condition of increasing disorder and randomness. In thermodynamic terms, entropy must increase for spontaneous change to occur in an isolated system.

Power The rate of energy transformation over time. The watt (W) is the common SI unit of power, where 1 W equals the power expended by the transformation of 1 J s⁻¹.

Patterns and Scale of Human Energy Use

We use energy to meet subsistence needs and to fulfill non-essential wants. In a subsistence society, a farmer burns wood to cook the day's meals. In an industrial society, people drive a car to go see a movie. Yet the forms of energy involved in these activities – wood, gasoline, electricity – merely comprise the means to end-uses – cooking, driving, operating a movie theater – that ultimately provide desired services – food, transportation, entertainment.

As used by humans, energy falls into two broad categories: industrial and traditional. Industrial energy includes those forms of energy generally transformed in bulk at centralized facilities by means of complex technology. In general, these forms fuel the technologies developed since the Industrial Revolution. The major forms of industrial energy are oil, coal, natural gas, nuclear, and hydroelectric. Industrial energy also includes other technologically complex renewable energy systems, including solar photovoltaics, wind turbines,

geothermal systems, and biofuels. Cogeneration systems that produce electricity and industrial heat from natural gas and hybrid gasoline-electric vehicles combine two forms of energy transformation to increase overall efficiency.

Traditional energy includes those forms generally dispersed in nature and utilized in small quantities by rural people. The principal forms are firewood, charcoal, crop residues, dung, and small water and windmills. Because traditional energy sources occur widely and because their transformation does not rely on complex technology, they comprise the most important sources for rural people in the less industrialized regions of the world. A rural household generally harvests traditional energy sources for its domestic needs. Because no commercial transaction occurs in these situations and because most governments do not regulate the use of traditional sources, official statistics do not closely track traditional energy use.

Traditional energy is a form of renewable energy, which includes forms of energy whose transformation does not

consume the ultimate source of the energy. Renewable energy harnesses solar radiation, wind, water movement, and cold and hot reservoirs in water and geologic strata. The major forms of renewable energy are solar, wind, geothermal, hydropower, and biomass. Conversely, nonrenewable energy systems consume the very source of the energy, primarily oil, coal, natural gas, and nuclear fuel.

In addition to traditional energy and industrial hydroelectric, renewable energy sources include technologically complex systems: solar photovoltaics, wind turbines, geothermal systems, and biofuels. These systems require complex machinery associated with industrial energy, yet depend only upon nondestructive methods of harnessing natural energy sources.

World energy use has increased substantially in the past 150 years (Figure 1). In the twentieth century, energy use increased by a factor of 12. During this time, the world witnessed an explosion in the use of fossil fuels, while renewable energy use increased slightly.

In 2008, the world used energy at a rate of 16.2 trillion watts (16.2 TW) (Table 1). As a comparison, this rate of energy use is equivalent to the power drawn continuously by 1.1 trillion compact fluorescent light bulbs rated at 15 W. As another comparison, world energy use in 2008 required the equivalent of the continuous output of 16,000 standard 1 GW nuclear plants.

The world uses renewable energy sources for 12% of its energy (Table 2). The rate of hydroelectric energy use (Tables 1 and 2) is equal to the hydroelectricity output. Unlike fossil fuel combustion systems, hydroelectric systems do not waste energy as heat. If an equivalent amount of fossil fuel were used to generate the 0.4 TW generated by hydroelectric plants, then the world rate of energy use would total 16.8 TW. Thus, hydroelectric displaces 0.6 TW of fuel use and the impacts from that amount of industrial energy transformation.

The world depends on industrial energy for 90% of its energy use. Fossil fuels and nuclear are the primary industrial energy sources. Traditional energy comprises approximately

one-tenth of world energy use. Countries in Africa, Asia, and Latin America account for the majority of world traditional energy use, with firewood and charcoal as the main sources.

While the United States (U.S.) is home to 4.5% of the world's population, it uses 19% of the world's energy (IEA, 2010). The U.S. fraction of global energy use has decreased steadily in the twenty-first century because of large increases in other countries, especially the People's Republic (P.R.) of China, where energy use has grown to the amount used in the U.S. (IEA, 2010).

One measure of energy efficiency is energy use per person. In 2008, average world energy use was 2400 W person⁻¹ (IEA, 2010). Average U.S. energy use (10,000 W person⁻¹) exceeds energy use per person in many other industrial countries, for example, France (5500 W person⁻¹). On average, each person in the U.S. uses six times the amount of energy as each person in Brazil (1700 W person⁻¹) and 15 times the amount of energy of each person in India (700 W person⁻¹) (Figure 2a).

Another measure of energy efficiency is energy intensity, the amount of energy used per unit of economic production. In 2008, average world energy intensity was 0.25 W \$⁻¹ of gross domestic product (GDP), adjusted for purchasing power parity (IEA, 2010). U.S. energy intensity matched the world average. The U.S. has steadily increased its energy efficiency for decades, although it still is less efficient than many other industrial countries, for example, the United Kingdom (0.15 W \$⁻¹) (Figure 2b).

In 2008, the world used 37% of energy for industry, 36% for the commercial and residential sectors, and 27% for transportation (IEA, 2010). In 2009, U.S. energy end-uses were: industry 30%, commercial 19%, residential 22%, and transportation 29% (U.S. Department of Energy, 2010). Globally, a third of energy goes to electricity generation, mainly from coal, hydroelectric, and nuclear. Power plants release two-thirds of that as waste heat (see the next section). In the U.S., personal cars use half of all transportation energy.

The traditional energy sources of firewood and charcoal mainly serve the end-uses of cooking and heating. Cooking 1 J

Figure 1 World energy use 1850–2009 (data from WEC and IIASA, 1995; BP, 2010; Food and Agriculture Organization (FAO) FAOSTAT <<http://faostat.fao.org>>; International Energy Agency (IEA) Statistics <<http://www.iea.org/stats>>). Because of a difference in FAO and IEA estimates of wood and biomass use, total 2008 energy use using FAO data is lower (15 TW) than total energy use using IEA data (16.2 TW).

of food requires approximately 2 J of firewood or 8 J of wood converted to charcoal. Consequently, rural people use 1–2 kg wood person⁻¹ day⁻¹, a rate of energy use of 250–500 W person⁻¹ (FAO, 2009). Only 20–40 W person⁻¹ enters the cooked food and warmed people because open fires diffuse the rest as waste heat (Gonzalez, 2001).

In urban areas of nonindustrial countries, people often rely on charcoal for energy. Even though the conversion of wood to charcoal releases waste heat, the end product has a higher energy density than firewood, making charcoal easier to store and transport. Urban people use 100–150 kg charcoal person⁻¹ year⁻¹, requiring 800–1200 kg wood person⁻¹ year⁻¹. The ultimate energy end-use is 30–45 W person⁻¹.

Implications of the Laws of Thermodynamics

The First Law of Thermodynamics states that energy is not created or destroyed, only converted between different forms. This is the principle of conservation of energy (Table 3). The First Law means that any energy that a process does not convert into useful forms will go into useless forms. Humans dump this waste energy into the environment.

The Second Law of Thermodynamics states that any system will tend to change toward a condition of increasing disorder and randomness. This is the principle of increasing entropy (Table 3). The Second Law means that no energy transformation can convert 100% of one energy form completely into a useful form. The process will always waste energy in forms that are unrecoverable due to the disorderliness or randomness of the waste energy forms. Therefore, the fewer energy transformations that a system performs, the fewer chances it creates for Second Law energy losses.

For example, the objective of an automobile's internal combustion engine is to convert the chemical energy in the covalent bonds of hydrocarbons in gasoline to heat energy in an expanding fuel–air mixture in the piston to kinetic energy in the drive shaft to kinetic energy in the main axle. No matter how efficient an engine and automobile can be, combustion processes will always waste energy as heat in the friction of engine parts, sound in the banging of vehicle components, heat in the friction of tires on the road, kinetic energy of the wind displaced by the vehicle, and countless other unrecoverable losses.

As another example, the objective of a coal-fired electric power plant is to transform the chemical energy in the covalent bonds of hydrocarbons in coal to heat energy in the boiler to heat energy in steam to kinetic energy in the turbine fan to electromagnetic energy in the generator coil. Along the way, the conversion processes lose energy as light and sound of the boiler fire, vibration of turbine parts, heat of power plant components, and, most of all, waste heat carried by the power plant cooling water.

Theoretically, the maximum efficiency across a heat gradient is the Carnot efficiency:

$$\eta = \frac{\text{Temperature of heat sink}}{\text{Temperature of transformation process}}$$

with temperatures in Kelvin (K).

For a coal-fired power plant, materials limit boiler temperatures to 1000–1200 K. At an ambient environmental temperature of 293 K (20 °C), the maximum efficiency will be 70–75%. Typically, coal plants only achieve efficiencies of 30–35%, releasing two-thirds of the total as waste heat.

Biodiversity Impacts of Industrial energy

Oil

The major impacts of oil on biodiversity come from a fuel cycle and end-uses that range over vast areas. Exploration, drilling, crude oil transport, refining, and combustion in vehicles alter terrestrial and marine habitat and pollute air, land, and water.

Petroleum, or oil, consists of a complex mixture of hydrocarbons formed over geologic time from organic matter compressed under anoxic conditions. The most important chemical constituents are alkanes (e.g., octane and methane) and aromatic hydrocarbons (e.g., benzene and toluene).

Oil deposits originated in aquatic vegetation deposited in inland seas and coastal basins during the Cretaceous period 100 million years ago. In the early stages of formation, bacteria initiated the anoxic reduction of the organic matter. Over time, pressure and temperature replaced microbial activity as the primary agent of transformation. Eventually, these forces drove off most of the water, oxygen, and nitrogen in the condensate, leaving oil compounds enriched in carbon and hydrogen. Dispersed between sediment granules, the oil eventually migrated to low-pressure geologic traps at depths of 1–7 km. On average, the stoichiometric composition of crude oil is CH_{1.5}, with a small amount of sulfur.

Petroleum exploration involves geologic surveys over extensive areas, often with low human population densities and relatively undisturbed natural communities. Exploration brings vehicle traffic and construction activity, generating local disturbances, yet the most serious impacts occur with seismic detection. This involves controlled detonations along lines or at points so that seismometers can extrapolate the layout of subsurface formations. These activities destroy vegetation, disturb ground-nesting birds and other wildlife, and fragment habitat. If these activities disturb animal behavior during breeding periods, the impact can last over many growth cycles.

Table 3 Formulations of the First and Second Laws of Thermodynamics

	First Law	Second Law
Universal	The total energy in the universe is constant	All physical processes proceed such that the entropy of the universe increases
Concise	Energy is conserved	Entropy increases
Colloquial	You can't get something for nothing	You can't even break even

Based on original formulations by John P. Holdren.

Since the drilling of the world's first commercial oil well in Titusville, Pennsylvania in 1859, oil fields have grown to cover vast areas, especially in the Middle East, North America, Russia, Mexico, Venezuela, and Nigeria. Construction of oil well pads, buildings, roads, electricity and water lines, and other infrastructure destroys vegetation and natural habitat. Roads and other linear infrastructure fragment a landscape that extends outside core areas of operation. For example, while the core infrastructure at the Prudhoe Bay field, Alaska (opened for drilling in 1968) covers 70 km², the 2000-km network of roads, short-distance pipelines, and electric lines cover 2600 km² of Arctic tundra. Proposed oil exploitation in the

Arctic National Wildlife Refuge in Alaska would further fragment the Arctic ecosystem.

Hundreds of thousands of kilometers of pipelines carry oil and refined products around the world, fragmenting and polluting natural areas. For example, the 1000 km pipeline for the Chad–Cameroon petroleum project sliced through intact tropical forests and attracted new migrants who cleared land for agriculture. The 700-km Camisea natural gas pipeline in Peru cut across Amazon rainforest, fragmented habitat, spilled gas liquids, and eroded soil into rivers.

To mitigate environmental impacts of the 1300-km Trans-Alaska pipeline and adjacent access road (operations started in 1977), oil companies integrated a set of environmental protection features. To prevent thawing of permafrost, brackets elevate 700 km of pipeline to heights of 3 m. Pipes at the bracket legs dissipate heat generated by the friction of oil passing through the pipe. Elevated sections provide passages for caribou (*Rangifer tarandus*). Bridges carry the pipeline over 800 streams. Zigzags along the pipeline translate the longitudinal movement of pipes expanding under heat to lateral movement, reducing the risk of leakage.

Routine drilling operations produce air and water pollution. Serious water pollution comes from drilling muds, a mixture of water and low-molecular-weight oil that drillers pump down to the drill bit to carry away rock cuttings, keep the bit from overheating, and protect the drill shaft from surrounding rock. Used muds contain bits of metal and trace metals mobilized from drilled rock.

All stages of oil production, from drilling to end-use, spill oil into surface and ground waters. Oil spills into oceans and freshwater bodies average 1.3 million tons year⁻¹ (NRC, 2003). Approximately 15% of spilled oil comes directly from oil wells, pipelines, and supertankers, 40% comes from non-point urban runoff, and the remaining comes from natural seeps. During oil production, spills occur at well blowouts when equipment fails to contain naturally high fluid pressures in oil-bearing strata. Spills also occur along the long lengths of pipeline from the wellhead to tank farms to supertanker ports to refineries to gas stations. Pipes, valves, and tanks leak from fatigue and from human error. The most catastrophic accidental oil spills in history have occurred from offshore oil wells and supertankers (Table 4).

Oil floats on top of water. Gravity and wind will spread a floating slick out to a thickness of 0.5–10 µm. Patches

0.1–5 mm thick can cover just 10% of the total slick area, yet contain 90% of the total slick volume. Some oil dissolves and emulsifies into the water column, forming emulsions containing 80% H₂O. Oil will generally not sink to depths below 20 m. Recovery teams can deploy an array of countermeasures that includes booms, skimmers, sorbents, pumps, burning, and surfactants for chemical dispersion.

Exposure to sunlight initiates photolysis of hydrocarbons into lower molecular-weight compounds. Heterotrophic bacteria will also oxidize hydrocarbons to smaller compounds, CO₂, and water. The lightest hydrocarbons and aromatic compounds (e.g., benzene) volatilize. Loss of the lighter fraction leaves the remaining slick more viscous over time. This thick oil forms tar balls and pancake-like forms. Some oil will sink into sediments; other oil will coat beaches; a fraction of oil will remain suspended in the water column for years.

Oil kills birds by coating, matting, and waterlogging their feathers. The water repellency, buoyancy, and insulating properties of plumage derive from an orderly arrangement of feather barbules and barbicels. Contact with oil disrupts these arrangements. Soaked birds can die of hypothermia and drowning. Survivors remain at risk for chronic exposure to toxic organic compounds through ingestion, inhalation of fumes, or absorption. Moreover, eggs are highly sensitive to contact with oil.

Many of the aromatic hydrocarbons in petroleum, including benzene, toluene, xylene, and phenols, are lethal to animals on contact and carcinogenic under chronic exposure. Moreover, polycyclic aromatic hydrocarbons bond to lipophilic sites, an affinity that concentrates these compounds in body tissues as they move up the food chain. Even when not deadly, sublethal disruption of physiology or behavior reduces resistance to infection and induces stress.

Oil obliterates the insulating properties of marine mammal pelage, leaving animals to die of hypothermia. In addition, oil can clog the nostrils of seals, causing them to suffocate. Whales, insulated by layers of oily blubber, not hair, resist the effects of oil. Marine mammals may experience chronic problems after a spill because oil can accumulate in bile and fatty tissues.

Important fisheries often lie over high-yield offshore oil fields on the continental shelves. Oil spills kill fish directly and chronic effects reduce fitness years after initial exposure. Oil at the air–water interface acts as a physical barrier that impedes gas exchange. Under a thick slick, fish larvae can suffocate.

Table 4 Most voluminous oil spills since 1960

Rank	Incident	Volume (million liters)	Date
1	Persian Gulf War	900	26 January 1991
2	Deepwater Horizon unit, Macondo well, Gulf of Mexico	700	20 April 2010

Source: Etkin, DS (1999) Historical overview of oil spills from all sources (1960–1998). *International Oil Spill Conference*, paper no. 169; Crone TJ and Tolstoy M (2010) Magnitude of the 2010 Gulf of Mexico oil leak. *Science* 330: 634, and International Tanker Owners Pollution Federation (ITOPF) (2010) *Oil Tanker Spill Statistics: 2009*. London: ITOPF.

Fish eggs, which often float at the sea surface, and fish larvae, which are often distributed in the upper water column, both occur in the areas of high oil concentration. Hydrocarbons damage eggs on contact. Oil concentrations will quickly exceed the LC_{50} for fish larvae of 1–10 ppm. The early-life stages of intertidal-spawning fish are especially susceptible.

Over time, tidal action coats the shore of the intertidal zone in a band of oil. This oil ring smothers intertidal invertebrates, crustaceans, mussels, barnacles, limpets, and algae. Oil will asphyxiate filter feeders.

Oil spills also damage phytoplankton and other marine plants. Because oil absorbs photosynthetically active radiation, a coat of oil will hinder plant growth and increase plant tissue temperature. Aromatic hydrocarbons may disrupt the orderly arrangement of grana in chloroplasts. Blue-green algae often bloom at oil spills, producing anoxic conditions.

The largest accidental oil spill in the world began with the 20 April 2010 blowout of the Deepwater Horizon mobile offshore drilling unit and the Macondo oil well in the Gulf of Mexico, off the coast of Louisiana, USA. A drilling pipe extended from the Deepwater Horizon on the ocean surface 1500 m to the Macondo wellhead on the ocean floor and 5600 m more to the oil reservoir. After the failure of a blowout preventer device at the wellhead, oil and natural gas shot up to the Deepwater Horizon and ignited in a massive explosion that killed 11 people and sunk the unit 2 days later. For 84 days, the well spilled 4.4 ± 0.9 million barrels of oil (700 ± 140 million liters) into the Gulf of Mexico (Crone and Tolstoy, 2010). Direct observations and modeling estimated the fate of the oil as: recovered 16–17%; burned 5–6%; skimmed 2–4%; chemically dispersed 10–29%; naturally dispersed 12–13%; evaporated or dissolved 20–25%; and washed up on coast, sunk due to sedimentation, exported from area in ocean currents 11–30% (Federal Interagency Solutions Group, 2010).

To reduce the amount of oil that could reach beaches, crews released 7 million liters of chemical dispersants, a record amount, at the wellhead and on the surface of the Gulf. As a consequence, much of the oil remained in the water column, increasing contact to and ingestion of oil by marine animals. U.S. Fish and Wildlife Service counts indicated that laughing gulls (*Larus atricilla*), northern gannets (*Morus bassanus*), brown pelicans (*Pelecanus occidentalis*), and royal terns (*Sterna maxima*) had the highest numbers of oiled birds, of over 100 species recorded. Also, leatherback sea turtles (*Dermochelys coriacea*), an endangered species, were oiled and biologists relocated nests of Kemp's ridley sea turtle (*Lepidochelys kempii*), another endangered species, to reduce the chance of exposure to spilled oil. The Gulf provides important marine habitat for sperm whales (*Physeter catodon*), an endangered species, bottlenose dolphins (*Tursiops truncatus*), and other marine mammals. Oil also coated areas of coastal wetlands, damaging marsh plants. Continued contact with oil could cause chronic harm to coastal plant and animal species for years. On the Mexican side of the Gulf of Mexico, oil spilled from the Ixtoc I remains under rocks in some areas decades after the spill. In France, local marine species and oyster farms needed a decade to recover from the Amoco Cadiz oil spill.

The largest oil spill in continental U.S. waters occurred on 24 March 1989, when the supertanker *Exxon Valdez* ran aground in Prince William Sound, Alaska, and poured out 42 million liters

of crude oil. The spill caused acute damage to birds, marine mammals, and intertidal communities and caused chronic damage to fish species and intertidal and subtidal communities.

The spill occurred in early spring, just before the young of many wildlife species emerged to rejuvenate marine animal populations. Pacific herring (*Clupea pallasii*) were spawning inshore. Millions of pink salmon (*Oncorhynchus gorbuscha*) fry were soon to be washed from gravel spawning beds into the spring plankton bloom offshore. Harbor seal (*Phoca vitulina*) and sea otter (*Enhydra lutris*) pups were testing the frigid waters. Seabirds were beginning to converge on breeding colonies in the gulf. The *Exxon Valdez* spill killed more than a quarter of a million birds of over 90 species, including marbled murrelets (*Brachyramphus marmoratus*), bald eagles (*Haliaeetus leucocephalus*), puffins (*Fratercula* spp.), and loons (*Gavia* spp.). Exposure to toxics from the *Exxon Valdez* spill caused chronic problems in fish, with elevated egg, larvae, and adult mortality, larval deformities, and poor adult growth rates.

The high energy density and flexibility of liquid fuels refined from oil render them convenient for powering motor vehicles. Onshore refining of oil into other products generates liquid and solid waste that pollutes natural water bodies. Refining employs catalytic cracking of carbon-carbon bonds of long-chain alkanes to produce lower molecular-weight hydrocarbons. Refineries attempt to recover every possibly useful organic compound, from light products, such as methane, benzene, and kerosene, to medium weight products, like gasoline and diesel fuel, to heavy tars and asphalt. Unless treated, wastewater from these processes and from sulfur recovery will pollute surface waters.

Most constituents of petroleum and refined oil products volatilize easily, so each step of the petroleum fuel cycle generates air pollution. Methane, benzene, toluene, and other compounds evaporate from crude oil exposed to air. The major emissions from oil refineries are CH_4 , CO, CO_2 , H_2S , NO_x , and SO_2 .

This section has concentrated on the impacts from the core stages of the petroleum fuel cycle: exploration, extraction, transportation, and refining. Nevertheless, the entire life cycle, from manufacturing to disposal, of oil infrastructure generates air and water pollution and alters natural habitats. Combustion of refined oil products for automobiles, heating, and other end-uses generates the most serious emission of the fuel cycle, carbon dioxide, the principal greenhouse gas. Moreover, armed conflicts caused, in part, by efforts to control access to oil fields and refineries, directly harm human wellbeing and ecosystem health.

Natural Gas

Natural gas is a mixture of hydrocarbons that exists in a gaseous state at standard temperature and pressure. Methane (CH_4) is the main constituent, but the presence of higher molecular-weight alkanes, including ethane, propane, and butane, changes the average stoichiometric composition for natural gas, with water vapor removed to $0.79 CH_{3.62}$. Formed by the same processes that formed oil, natural gas is often found at the top of oil deposits. The most voluminous natural gas reservoirs occur in Cretaceous strata.

Land use changes caused by exploration and extraction of natural gas produce the same biodiversity impacts described for oil. In particular, exploration grids, roads, and other linear infrastructure fragment landscapes that extend far outside core areas of operation. Accelerated natural gas leasing in the intermountain region of the western U.S. since 2001 has created networks so dense that no undisturbed ecosystems remain in some areas, threatening grassland habitats and species such as the greater sage-grouse (*Centrocercus urophasianus*) and the pronghorn (*Antilocapra americana*).

In the nineteenth century, companies had not yet erected natural gas pipelines or processing facilities. Moreover, industry had not yet developed extensive technology that used natural gas. Because companies found natural gas uneconomical to exploit, they burned it off to reduce the risk of fire and explosion. Consequently, the entire history of natural gas production has flared the equivalent of 8 years worth of U.S. energy use (Boden *et al.*, 2010). In 2008, natural gas flaring globally wasted an amount of energy equivalent to a quarter of U.S. natural gas use, or all of the natural gas use of Latin America, or twice the natural gas use of Africa (Elvidge *et al.*, 2009). Currently, Russia and Nigeria flare the most natural gas.

Gas companies generally pump natural gas straight from the well to a processing plant, avoiding the need for storage facilities at the wellhead and reducing the potential for leakage. Gas companies generally divide natural gas into three fractions: natural gas liquids (NGL), liquified petroleum gas (LPG), and liquified natural gas (LNG). NGL consists of the higher molecular-weight fraction of natural gas that often settles out by gravity. Processing of natural gas from oil wells produces LPG. Finally, pressurization of natural gas produces LNG, a product that is expensive because of the special containers required for transport.

Hundreds of thousands of kilometers of natural gas pipelines destroy and fragment natural ecosystems and create avenues for people to settle and clear forests. Construction of specialized natural gas terminals can destroy or alter coastal ecosystems.

The major end-uses of natural gas, cooking and heating, burn the fuel directly with no further transformation. Electricity generation from natural gas employs a gas turbine, which directly uses the hot gas products of combustion to turn the turbine fan, eliminating the intermediate step of steam generation used in oil and coal-fired plants. Cogeneration plants increase the energy efficiency of gas turbine systems by utilizing the waste heat of gas turbines for space heating or industrial processes.

Extraction and combustion of natural gas pollute much less than extraction and combustion of oil. Because it exists in a gaseous state for much of the fuel cycle, natural gas exploitation does not produce significant amounts of water pollution. Yet, methane is a greenhouse gas with a global warming potential of 21, indicating an impact on global warming 21 times more intense than carbon dioxide. The combustion of methane also produces carbon dioxide and contributes to climate change.

Coal

Coal consists of hard carbonaceous material formed by compression and transformation of terrestrial plant matter rich in

cellulose, buried at the bottom of ancient freshwater swamps and bogs. The richest coal-bearing strata date from the Cretaceous period 100–200 million years ago and the Permian period 250 million years ago. Similar to the process of petroleum formation, deposited plant matter undergoes incomplete decay in anoxic conditions.

In geologic time, the pressure of overlying rock and the heat generated therein drive off oxygen and hydrogen, leaving thick seams of reduced carbonaceous rock containing much more organic than mineral matter. The average stoichiometric equation of coal is $0.75\text{CH}_{0.8}$, but elemental sulfur contaminates most coal deposits. The four major types of coal, in order of decreasing carbon content and increasing sulfur, are: anthracite, bituminous, subbituminous, and lignite. Bituminous coal is the most abundant type worldwide. Peat, the partially oxidized, moist, organic soil that forms in marshes and bogs, is an early precursor of coal. In certain regions, people burn peat for heating, cooking, and lighting.

The coal fuel cycle extends from extraction at the mine to combustion at a power plant to distribution across the electric grid to end-uses in lighting, heating, and all the other uses of electricity. Coal mines sprawl over vast land areas, including areas for excavation, dumps for extracted rock, and the support infrastructure of buildings, roads, and rail.

Deep and open pit mines remove huge amounts of rock, termed overburden, lying over the coal. Land over deep mines will sink, a process termed subsidence, physically changing a landscape. Underground coal fires in abandoned mines and refuse banks not only exacerbate subsidence, but they also release CO_2 and other air pollutants.

Miners dump large amounts of unwanted extracted rock, termed mine tailings, in abandoned parts of active mines or on the surface. Pyrite (FeS_2) usually comprises a significant fraction of the tailings. The reaction of water and pyrite produces sulfuric acid (H_2SO_4). In addition to being poisonous to plant and animal life, sulfuric acid mobilizes other toxic substances. The leaching of acids, trace metals, dissolved solids, and toxic organics produces a liquid known as acid mine drainage that can devastate surface waters. Selenium and cadmium often occur in high concentrations in tailings, so acid mine drainage can initiate the bioaccumulation of these trace metals in the surviving sections of the food chain.

Surface mining consumes vast tracts of land. Heavy machinery removes the upper layer of a landscape to expose relatively shallow coal seams, completely destroying the mined area. Although coal companies generally fill the overburden back into the mined area and replant it, strip-mined land can never completely recover its original characteristics. In addition, disturbance creates opportunities for invasive species to expand where perennial native plant species may have dominated. Rodents and other animals that adapt readily to human disturbance also take advantage of reclaimed areas.

Coal mines often impound surface streams to satisfy the large water needs of mine operations. These needs include water cannon drilling, transport by slurry, fugitive dust spraying, coal washing, and size sorting.

Mines crush and screen coal for uniform size, then wash and dry the coal for open-air storage. Fugitive emissions from these processes consist of particulates that coat any exposed surface, blocking photosynthetically active radiation from

plants, contaminating food and water sources for animals, and acidifying affected soil. Leaching of toxic substances from coal storage piles adds to the pollution of surface waters. Rail transport provides the most cost-effective means of moving the bulky commodity of coal, but fugitive emissions from unit trains increase particulate concentrations in rail corridors. To save money on rail transport, many utilities build electric power plants next to the mine and transmit the electricity by wire. In certain regions, this shifts the pollutant load from urban to rural areas.

Most coal goes to generate electricity. A conventional power plant burns coal in a boiler to boil water that circulates through a closed loop of pipes. The steam from the boiler enters a turbine to turn huge fans that power an electric generator that converts kinetic energy to electric energy. The generator exploits a physical principal in which the movement of a conductor across a magnetic field creates electric current in the conductor. In a coal-fired electric generator, the conductor consists of stationary coils of wire surrounding a magnet on a shaft rotated by the turbine fan. Much of the steam that moves through the fan transfers its heat energy to the kinetic energy of the fan, causing the steam to condense back to water. A condenser will then allow heat to transfer from any steam that continues past the turbine to an external supply of cold water. The water in the internal loop from the condenser returns back to the boiler to enter the steam cycle again.

Coal combustion releases CO, CO₂, SO₂, NO_x, particulates, fly ash, arsenic, cadmium, chromium, mercury, and selenium. Approximately 40% of anthropogenic CO₂ emissions come from burning coal, while coal burning produces approximately 80% of human SO₂ emissions. Consequently, greenhouse gases and acid precipitation may be the agents of coal's most extensive environmental impacts.

Slag remaining from burned coal contains high amounts of trace metals, especially cadmium and mercury. In addition, sludge from flue gas desulfurization units, the pollution control devices known as scrubbers, contains trace metals and toxic organics. Disposal of sludge can pollute soil and water.

Internal steam turbine water is the working fluid circulating from the boiler to the turbine to the condenser and back to the boiler. Cooling water is the medium that draws heat from the internal steam turbine water. In most conventional coal-fired power plants, the internal steam turbine water remains separate from power plant cooling water. A typical condenser consists of copper coils, carrying cooling water, that pass through larger structures carrying the internal steam turbine water. Heat passes from the steam turbine water through the walls of the copper coils into the cooling water.

A 1 GW coal-fired power plant typically uses 4 million m³ water per day for all operations, mostly for cooling. Consequently, electric utilities often build plants next to natural water bodies. Power plants use freshwater because of the corrosive effects of salt water. Water withdrawals alter the hydrology of a watershed and change water levels, surface area of mudflats, surface area of wetlands, and other important habitat characteristics that can strand hydrophilic plant species such as willows (*Salix* spp.) and harm fish and shorebird populations. Impingement on intake screens kills significant numbers of fish and other aquatic species. Organisms that get

through the screens can get entrained in the condenser, causing even greater mortality. The stress that any surviving organisms undergo reduces fitness considerably.

Industrial electric power plants (coal, oil, nuclear) generate three-quarters of the waste heat dumped into U.S. surface waters and into the atmosphere above the U.S. Once-through systems dump waste heat directly into local waters. Cooling towers systems dump waste heat into the atmosphere, condensing steam from the air. Cooling ponds provide a buffer for releasing some of the heat from cooling water into the atmosphere, reducing the temperature of cooling water before it enters surface waters.

Thermal discharges into freshwater and coastal zones cause many negative impacts on aquatic species:

1. Direct lethality to fish and crustaceans at water temperatures $\geq 35^\circ\text{C}$.
2. Decrease in dissolved oxygen.
3. Increase in metabolic rates and nutrition needs for fish and changes in nutrition requirements for other taxa.
4. Displacement of diatoms by green and blue-green algae.
5. Inhibition of vertical migration by zooplankton.
6. Thermal plumes blockage of migratory fish movement.
7. Avoidance of warm areas by migratory waterfowl.
8. Early emergence of aquatic insect adult life stages into inhospitable environmental conditions.
9. Copper contamination from condenser coils.

Long-range transmission of electricity occurs across high-voltage lines strung on metal towers up to 60 m tall. The network of high-voltage electricity lines (230, 345, 500, 765 kV) in the U.S. stretches across 250,000 km and occupies more than 13,000 km² of land (U.S. Department of Energy, 2010). Clear-cutting of forest to create transmission corridors 30–60 m wide destroys vegetation. Maintenance periodically disturbs the corridors, favoring ruderal plant species and animals that adapt readily to human disturbance. Herbicides used for periodic clearing can kill pollinating insects and birds. Transmission line corridors fragment habitat and increase the area of habitat susceptible to edge effects while providing avenues for the dispersion of invasive weeds. Cleared areas can also block migrating land animals.

Short-range electricity transmission occurs across low-voltage lines strung on wood, metal, or concrete poles generally 5 m tall. Harvesting wood poles can produce all the potential biodiversity impacts of commercial logging, timber plantations, and milling. In many countries, utilities treat the wood with creosote to guard against insects and weather. Creosote, a by-product of crude oil refining, contains significant amounts of toxic organics that can leach and contaminate surface waters.

The materials and energy used to build the massive infrastructure of the coal fuel cycle produce wide-ranging environmental impacts. Because most coal goes to electricity generation, the end-uses of coal produce the environmental impacts associated with air conditioning, commercial machinery, residential appliances, and other electric devices. Owing to massive economic growth, P.R. China switched from a net exporter to a net importer of coal in 2009. Australia, Canada, Columbia, Indonesia, South Africa, and the U.S. export substantial amounts of coal to P.R. China. Environmental

impacts of coal mining and processing occur in the exporting countries while environmental impacts of coal burning occur in P.R. China and around the entire world due to the emission of greenhouse gases.

Nuclear Fission

Nuclear fission is the splitting of high-molecular-weight elements to release energy held by protons and neutrons in the nucleus of the atom. Uranium and plutonium are the elements that provide the most effective yield from fission. A fission reaction produces energy in the form of light, heat, motion of the fission products, and radiation. Radiation consists of kinetic energy of small molecules and atomic particles and electromagnetic energy of photons traveling at certain frequencies. When radiation passes through living tissue, the particles or photons impart their energy to atoms and molecules in the tissue, disrupting molecular and atomic structures.

Fission products emit radiation until they reach a stable atomic state. While the half-life of strontium-90 is 29 years and the half-life of cesium-137 is 30 years, plutonium-239 decays with a half-life of 25,000 years, and a quantity of iodine-129 will decay to half of its mass only after 17 million years. The similarity of the atomic structure of strontium to calcium increases the uptake of strontium by animals and its incorporation into bones.

Nuclear fission plants require highly processed uranium fuel. Uranium rests in geologic strata in the minerals uraninite and pitchblende. The isotope uranium-238 accounts for over 99% of the uranium in nature, but nuclear fission fuel requires the uranium-235 isotope. A standard 1 GW nuclear fission plant requires 150,000 Mt uranium-containing ore to fabricate enough fuel for 1 year. Milling, roasting, and acid leaching of the ore produces 150 Mt uranium oxide (U_3O_8) in a granular form called yellowcake as well as substantial amounts of ore tailings and chemical effluents. Fluorination of the yellowcake produces 188 Mt of uranium hexafluoride (UF_6).

Processors use one of three methods – gaseous diffusion, gas centrifuge separation, or liquid thermal diffusion – to divide UF_6 into separate fractions, one of which is enriched in a higher concentration of uranium-235 than found in nature. Nuclear fission for electricity generation requires enrichment to 2–3% uranium-235. Continuation of the process produces material enriched to 97–99% uranium for nuclear warheads.

The original 150,000 Mt of ore for a standard 1 GW nuclear fission plant has thus yielded 31 Mt UF_6 enriched in uranium-235. Fuel fabrication then produces 30 Mt of uranium dioxide (UO_2) pellets for use in the nuclear reactor core.

Mining and milling of uranium ore creates most of the same environmental problems described for deep coal mines and coal processing. Uranium conversion, enrichment, and fuel fabrication require toxic chemicals, including fluorine gas, which is lethal on contact to animals, damages vegetation, and forms toxic by-products.

In December 2008, 438 nuclear fission plants with a combined rated capacity of 372 GW were operating in 31 countries (IAEA, 2009). Among these, the U.S. operates 104 nuclear fission plants with a combined rated capacity of 101 GW.

Nuclear plants generate electricity in a steam cycle similar to the system in coal plants, except that nuclear fission is the source of heat for the boiler. Higher operating temperatures require more cooling water than a coal-fired plant of the same electricity generation capacity. A 1-GW nuclear fission plant requires 6 million m^3 of cooling water each day, so the effects of water intake and thermal discharge described in the section on coal are all greater with nuclear plants.

Because nuclear plants involve fossil fuel combustion only in construction and in support vehicles, they produce few direct air emissions. Nuclear plants, however, produce wastes that can remain radioactive for millions of years. Low-level wastes include reactor containment water, worker clothing, exposed tools, and plant fixtures irradiated for limited periods of time. High-level wastes consist of spent fuel and the fuel rods in which they are encased. The U.S. has not constructed a permanent repository for high-level wastes, which nuclear plants continue to store on site.

The greatest single release of radiation from a nuclear fission power plant came from the Chernobyl Unit 4 accident on 26 April 1986 in an area of the Republic of Ukraine that was in the former Soviet Union. Operator error combined with design aspects of the RBMK graphite-moderated reactor generated a nearly instantaneous catastrophic increase of thermal power and a steam explosion. The explosion destroyed the reactor and released 3% of the reactor fuel and up to 60% of the volatile products in the reactor core, mainly iodine-131, cesium-134, and cesium-137. The accident deposited radioactive fallout over the entire Northern Hemisphere.

Twenty-eight people died from acute radiation doses, while thyroid cancer has been found in at least 4000 people due to ingestion of iodine-131 (Chernobyl Forum, 2005). The Soviet government evacuated 116,000 people from a zone of 30 km radius and constructed a cement sarcophagus to contain the remains of the reactor. Increased risks of thyroid cancer and leukemia are possible for the 5 million people who lived in the contaminated parts of Belarus, Russia, and Ukraine.

Lethal radiation killed many conifers and small mammals within 10 km of the accident in the first few weeks. Radioactivity remains in trees and soil in the form of cesium-137. Grass, mushrooms, and berries continue to incorporate the isotope, perpetuating a source of exposure for people and wildlife that feed on contaminated plants. Atmospheric fallout from Chernobyl may also cause genetic abnormalities in the long term.

Hydroelectric

Hydroelectric systems harness the potential energy held by an elevated mass. The potential energy of water will convert to increased kinetic energy of the water when it runs to a lower elevation. A dam concentrates the difference in elevation, termed hydraulic head, in a spillway equipped with a turbine and an electric generator. The electricity immediately enters the electric grid. In this manner, a hydroelectric plant will generate electricity with few direct air emissions and little thermal discharge. The principal effects of hydroelectric plants come from the considerable alteration of topography and flow of a watercourse and the partial inundation of its watershed.

Besides the forced removal of people and inundation of homes, hydroelectric plants also cause significant ecological changes.

Over 45,000 large dams block rivers around the world, creating reservoirs that inundate up to 1 million km² (World Commission on Dams, 2000). In 2010, P.R. China completed filling the reservoir of the Three Gorges Dam, the hydroelectric plant with the highest generation capacity in the world (18.2 GW). The project has inundated 630 km² along 600 km of the world's third longest river, the Yangtze, and displaced 1.2 million people. In 1965, the Akosombo Dam on the Volta River in Ghana created Lake Volta, at 8500 km² the largest impoundment in the world.

Inundation of formerly dry land destroys vegetation and decreases the area of terrestrial habitat. Inundated forests represent ecosystem services forfeited and biomass wasted. A dam blocks nutrient-rich sediment that a river system would have deposited in floodplains, wetlands, and the outlet delta. Sediment fills the reservoir, impairs electricity generation, and traps rich organic carbon and other nutrients at the bottom of the reservoir. At the outlet delta, dams alter bay and estuary topography, reduce the area of mudflats and wetlands, and decrease the upwelling of nutrient-rich water. The Aswan High Dam in Egypt blocks 98% of the 120 million tons of sediment that the Nile River had carried each year, formerly depositing 10 million tons on the floodplain and delta. Consequently, soil depth has thinned and agricultural production has declined in the Nile Valley. Blockage of sediment and freshwater by the Akosombo Dam in Ghana has caused the decline of clams in the Volta estuary and barracuda (*Sphyraena barracuda*) in the Gulf of Guinea. The reduction of estuaries and mudflats at a dammed river's outlet delta renders the coast more susceptible to tidal erosion.

Utilities start and stop the flow of water based on electricity use and operational objectives. One operational objective, smoothing out extremes caused by natural flood regimes, changes the meandering and other channeling processes of a river. After the Glen Canyon Dam ended spring floods in the near downstream section of the Colorado River, sandbar erosion increased because the river did not flow fast or deep enough to move the amount of silt required for extensive sandbar formation. The resulting disappearance of some riparian tree species has led to the decline of southwestern willow flycatcher (*Empidonax traillii*) and other birds. To mitigate the problem, the U.S. Department of the Interior began to stage controlled floods.

For some dammed rivers, the flow of water unburdened by silt can deepen the riverbed. The depletion of riverbed gravel can harm any species of fish, insect, mollusk, or crustacean that requires a gravel stream bottom to spawn. Many insect, amphibian, and fish species also use gravel areas for habitat or protection.

The depth of a reservoir will often keep water at a temperature lower than in the native river. For example, the Glen Canyon Dam changed the water temperature in the near downstream section of the Colorado River from a range of 0–27 °C to a relatively constant 8 °C. This has contributed to the extinction of Colorado squawfish (*Ptychocheilus lucius*), roundtail chub (*Gila robusta*), and bonytail chub (*Gila elegans*) and the endangerment of five other fish species. Whereas

release water is clear, reservoir water often becomes slightly turbid and eutrophic.

Impacts of dams on anadromous fish relate to the migratory behavior and timing of the life cycles of these unique species. Dams erect a hazard for the downstream migration of young fish and block the upstream migration of adults. Moreover, salinity and temperature adaptations in anadromous fish occur on a precise schedule, making long delays lethal. Also, disoriented and fatigued fish more easily fall prey to predation. Despite the deployment of extraordinary means to facilitate fish migration, including fish ladders, elevators, and trap-and-haul trucking, dams have eliminated anadromous fish from many rivers. Runs of Atlantic salmon (*Salmo salar*) and American shad (*Alosa sapidissima*) have disappeared from many rivers in the northeastern U.S. In the Columbia River Basin in the northwestern U.S., overfishing, pesticide runoff, and hydroelectric plants have endangered populations of Snake River sockeye salmon (*Oncorhynchus nerka*) and Snake River chinook salmon (*Oncorhynchus tshawytscha*).

Exotic fish species introduced into reservoirs for sport fishing often outcompete native species. In the 1350 km² reservoir on the Brazil–Paraguay border behind the Itaipu Dam, the hydroelectric plant with the second highest generation capacity in the world (12.6 GW), a nonnative species, curvina (*Plagioscyon squamosissimus*), has become the second most numerous fish species.

Polychlorinated biphenyls (PCBs) from electric transformers and oil leaking from machinery comprise the worst direct industrial pollution from dams. These substances and toxic organic chemicals accumulate in sediments and magnify up the food chain. Impingement of aquatic organisms on intake screens and entrainment through turbines kills many individuals and causes stress and injury in survivors.

Materials and energy used to construct the massive infrastructure of the hydroelectric energy cycle produce wide-ranging environmental impacts. In addition, end-uses of hydroelectricity will produce the environmental impacts associated with air conditioning, lighting, commercial production machinery, residential appliances, and other electric devices. Because smelting aluminum from bauxite ore requires large amounts of electricity, aluminum smelting comprises an end-use closely tied to the hydroelectric option. Air emissions from smelters include CO, CO₂, particulates, NO_x, and trace metals. Major water pollutants include trace metals and sulfates.

Renewable Energy Technologies

Renewable energy includes those forms of energy whose transformation does not necessarily consume the ultimate source of the energy, harnessing instead solar radiation, wind, the motion of water, or geologic heat. This section covers renewable energy technologies, including solar heating, solar thermal electric, solar photovoltaics, electric wind turbines, geothermal, biomass-to-energy (electricity and heat), and biofuels. These are renewable energy systems that depend on complex technology, so they are forms of industrial energy. The section on traditional energy covers the simpler forms of renewable energy – firewood, charcoal, and small water and windmills.

Forms of renewable energy generally require specific site characteristics, exhibit high temporal variability in availability, and capture diffuse flows. Except for biomass-to-energy (electricity and heat), renewable energy technologies do not involve combustion, so they do not directly produce much air pollution. The principal environmental impacts come from fabrication, installation, and maintenance of renewable energy devices.

Solar energy systems fall into two categories: passive and active. Passive systems consist of architectural forms that more effectively follow the diurnal and seasonal patterns of sunlight for the efficient heating and cooling of a building. Passive systems use the natural phenomena of radiation and convection. Active systems use moving devices to achieve heat transfer. Solar heating systems include passive solar building designs and simple active systems that use pipes or other collectors to heat water for residential or commercial use. Solar heating systems are nearly environmentally benign.

Complex active solar systems include solar thermal electric and photovoltaic systems. Solar thermal electric systems, also known as concentrating solar power systems, use arrays of reflective parabolic or trough collectors to focus sunlight on a water boiler to power a turbine to generate electricity. Photovoltaics are solid-state devices in which photons stimulate the emission of electrons and semiconductor materials channel the electrons for collection. They are flat rectangular chips placed into long flat arrays. Photovoltaics directly convert sunlight to electricity with no moving parts, except for motors that move the arrays to track the sun. These systems use water to wash photovoltaic surfaces.

The two types of complex active solar systems require vast areas of land for the solar collectors or the photovoltaic arrays. In 2010, the U.S. Government permitted 3.6 GW of solar thermal electric and photovoltaic plants in California and Nevada and advanced plans for large solar plants throughout the southwestern U.S. Many of these projects will occupy and possibly damage natural ecosystems and habitat for threatened species such as desert tortoise (*Gopherus agassizii*). Because solar is most economically feasible in sunny areas, solar sites are generally arid and water is scarce. Water withdrawals for turbines and for washing collectors and arrays contribute to water flow reductions that can harm aquatic ecosystems.

Concentrating solar power systems are industrial scale plants that alter extensive areas of natural land far from energy users. In contrast, decentralized photovoltaic arrays above parking lots in urban areas have emerged in California as a more environmentally sound and economically feasible energy solution. Numerous colleges and schools, mainly in the San Francisco Bay Area, have erected solar arrays above parking lots. These projects use land that has already been urbanized and is close to the energy users, reducing transmission infrastructure and electricity losses. In some cases, solar arrays can provide for all school electricity uses. These systems demonstrate the solar potential of urban areas, especially parking lots and building roofs.

Fabrication of photovoltaic cells produces toxic environmental impacts. Mining the quartz base material of a photovoltaic cell produces many of the same impacts on aquatic and terrestrial biodiversity described for coal mining. Production of metallurgical grade silicon requires the refining of the

quartz to 99% purity at 3000 °C in an electric arc furnace. Production of semiconductor-grade silicon takes place in a fluidized bed reaction of the silicon with hydrochloric acid. The process produces semiconductor-grade polycrystalline silicon by electrical heating of the semiconductor-grade silicon at 1000 °C and vapor deposition onto a silicone substrate. Remelting the polycrystalline silicon produces a form that can grow into crystals. Precision saws cut these crystals into wafers 0.5 mm thick. Robotic devices wire and encapsulate the cells in glass 3 mm thick.

Trace metals are used to dope the semiconductor material for the principal types of photovoltaic cells: cadmium telluride, copper indium diselenide, gallium arsenide, and gallium indium phosphide. Trace metals in these compounds, chlorinated organic solvents, and phosgene gas all produce hazardous air, water, and solid wastes that can be lethal on contact or carcinogenic in small doses.

Biomass-to-energy plants are facilities that convert waste wood from lumber mills, wood from dedicated plantations, agricultural waste, or municipal waste to electricity either through direct combustion of biomass in low-pressure boilers to power electric steam turbines or through gasification of organic matter into methane to power natural gas electric turbines. Biomass-to-energy plants often employ cogeneration to provide process heat for an adjacent industrial facility. The section on coal details the negative effects of electric turbines and condensers that are also components of biomass-to-energy systems.

Utilities in Brazil generate electricity and cogenerate heat from the organic wastes (bagasse) from sugar cane and orange juice processing. Landfills around the world use networks of collection pipes to capture methane released by decomposing municipal waste and send the methane to natural gas electric turbines. Most biomass-to-energy plants use material that otherwise would be wasted and discarded in landfills. The biomass would otherwise oxidize and release its energy as waste heat. The productive reuse of waste products in biomass-to-energy production therefore reduces the environmental impact of the disposal of biomass waste.

Experimental schemes, however, that grow wood or agricultural crops specifically to burn for electricity generation, can produce negative environmental impacts if the schemes use conventional fossil-fuel-powered machinery and energy-intensive fertilizers. Indeed, energy-intensive methods could expend more energy in the cultivation and processing of energy crops than the amount of energy generated by burning the biomass to generate electricity. The principal species used by such schemes include short rotation trees such as poplars and aspen (*Populus* spp.), grown at densities of 1600–5000 trees ha⁻¹, and switchgrass (*Panicum virgatum*). An energy crop can damage natural ecosystems if it is grown in monoculture or if vegetation is clear-cut to prepare for the crop. If previous land uses were less environmentally sound than the energy crop, then the crop could mitigate the impacts of the previous land use.

Conversion of biomass into alcohol fuels, known as bio-fuels, also requires the dedicated growing of energy crops, primarily corn, palm trees (for palm oil), soybeans, and sugar cane. Fermentation of cellulose and other complex carbohydrates produces ethanol, which certain engines burn

straight or mixed with gasoline. Otto Cycle engines burn neat ethanol, a mixture of 96% ethanol and 4% water. Modified conventional automobile engines can burn gasohol, a mixture of 78% gasoline and 22% ethanol. The U.S. produces ethanol mainly from corn. Brazil produces enough ethanol from sugar cane to provide for 10% of the country's energy use.

Biofuel production that uses conventional fossil-fuel-powered machinery and energy-intensive fertilizers can expend more energy in the cultivation and processing of energy crops than the amount of energy contained in the final product. Moreover, combustion of fossil fuels and energy use for inorganic fertilizer production generate the negative impacts identified in previous sections. Because the combustion of ethanol mainly produces CO₂ and water and much smaller amounts of hydrocarbons and NO_x than gasoline combustion, ethanol produced by nonfossil fuel-intensive processes can mitigate the most harmful direct effects of oil production and use.

Conversion of the principal areas of rainforest, peatlands, and grasslands to produce biofuels in Brazil, Southeast Asia, and the U.S. could potentially release 20–400 times more CO₂ than the displaced fossil fuels in the next half-century (Far-gione *et al.*, 2008). In contrast, biofuel from waste biomass or biomass grown on abandoned agricultural lands planted with perennials can produce less CO₂ than displaced fossil fuels.

Since the 1980s, electric utilities have used wind turbines to power electric generators. Early electric wind turbines were typically 10 m tall with rotors diameters of 5–10 m and electricity generation ratings of 100–300 kW per turbine. Wind turbines are now typically 50–100 m tall with rotor diameters of 30–100 m and electricity generation ratings up to 2.5 MW per turbine. Offshore wind turbines are generally larger, to take advantage of steady winds and economies of scale.

Wind farms of hundreds of turbines occupy considerable land and offshore areas. The first large-scale wind farms operated in the Altamont Pass in the San Francisco Bay Area, California, the Tehachapi Pass in Southern California, in the Netherlands, and Denmark. They have now become widespread throughout the world.

Wind farms fragment terrestrial habitats and access road networks cause soil erosion. Wind turbines kill substantial numbers of birds and bats. Rotors produce substantial noise. Offshore wind turbines can act as artificial reefs, potentially changing local marine food webs. Electromagnetic fields from turbines and underwater cables can disrupt marine mammal navigation abilities.

Wind turbines could potentially produce all of the world's electricity. Wind turbines operating at only 20% of their rated capacity (due to diurnal and seasonal wind cycles, some turbines only turn 20% of the time) on available nonforest, ice-free, and nonurban areas could potentially generate electricity at a rate of 100 TW for the world and 8 TW for the contiguous U.S. (Lu *et al.*, 2009).

Geothermal devices capture heat or cold stored underground and directly use the heat or cold for different purposes on the surface or process the heat through turbines to produce electricity. The U.S., P.R. China, and Sweden led the world in installed capacity of geothermal direct use systems in 2010 while the U.S., Philippines, and Indonesia led in installed capacity of geothermal electric systems (REN21, 2010).

Geothermal direct heat systems pipe water from underground hot geologic formations to the surface to heat greenhouses, buildings, and fish farm ponds or to heat streets and sidewalks from below to melt snow and ice on the surface. Geothermal heating and cooling systems pump water or another working fluid through a closed loop of pipes and a heat exchanger in contact with shallow underground areas or water bodies that maintain a relatively constant range of temperatures. In temperate zone residential geothermal systems, underground soil and rock are cooler than the surface in summer and warmer than the surface in winter. The heat exchanger cools the house in summer and transfers heat from the ground to the house in winter.

In the largest geothermal cold storage system in the world, the 2 GW capacity Alderney 5 project in Halifax, Nova Scotia, pipes take cold harbor water for 7 months and stores it in a field of 200 m deep boreholes that cool bedrock under a ferry terminal parking lot. A heat exchanger uses the stored water to cool a commercial and industrial complex in summer.

Geothermal electric systems capture the heat of hot geologic formations from a system of pipes sunk down into hot strata. These systems capture deep hot water or inject water so that it boils on contact with hot rocks and process the heat through turbines to produce electricity. These systems mobilize trace metals contained in certain geologic formations and release H₂S gas from geothermal deposits.

Biodiversity Impacts of Traditional Energy

The most important sources of traditional energy are firewood and charcoal, which is produced from firewood. Local people harvest firewood by coppicing shrubs and cutting branches from mature trees. Rural people in Africa, Asia, and Latin America generally avoid felling whole trees for domestic firewood because of the time and labor required to cut the tree and split the logs.

In semiarid areas of Africa, women prefer the straight, moderately sized branches that coppiced shrubs produce. Rural people go out in the dry season and coppice (cut at the base) small shrubs (family *Combretaceae*). Women carry branches back to the village and let them dry. Just before the first rains, men and women cut a store of firewood for the rainy season. This serves, first, to avoid cutting wood that is wet and difficult to burn and, second, to complete a time-consuming and strenuous chore before the exhausting and rushed rainy season.

Coppiced shrubs resprout in the rainy season and regrow branches in a year. When shrubs become scarce, women pull branches from adult trees, sometimes using long-handled hooks. This harms the growth potential of a tree by removing shoot apical meristem tissues and can yield thorny branches that are difficult to handle. When branches are depleted, women in semiarid areas of Africa fall back on noxious, dead stalks of spurge (family *Euphorbiaceae*). The last resort is animal dung.

While women carry firewood for rural use, rural people also load beasts of burden and carts to transport wood for sale in urban areas. In this way, a town or city can generate impacts far beyond its borders.

Wood contains energy at a density of approximately 15 GJ t^{-1} , one-third the energy density of oil. The relatively low-energy density of wood renders its transport onerous relative to the energy gained. Conversion of firewood to charcoal creates a product with double the energy per unit mass, but emits up to two-thirds of the energy contained in the original wood as waste heat. Charcoal makers cut down live and dead trees, targeting sturdy tree trunks. They pile the wood, cover it with soil to form a kiln 1–4 m in height and 1–3 m in diameter, and ignite a slow burn. Over 3–6 days, the wood converts to charcoal by partially anaerobic pyrolysis.

If wood harvesting for firewood or charcoal exceeds the natural regeneration of shrubs and trees, then wood harvesting will reduce vegetative cover. Reduction of vegetative cover and conversion of forested or wooded land to savanna or grassland comprise the principal potential impacts of traditional energy on natural ecosystems. People's preferences for certain species for firewood can also create a risk of overharvesting preferred species.

In some areas of Africa, Asia, and Latin America, international development agencies have funded the massive plantation of nonnative tree species for firewood production. Plantations that replace native forest or woodland eliminate natural ecosystems. In general, the biological and structural diversity of natural forests makes an area more resilient to fire, wind, and insect disturbances.

Natural regeneration of local species can restore native forest cover in ecosystems changed by overharvesting. Natural regeneration is a traditional practice in which farmers and herders protect and promote the growth of young native trees. Traditionally, local people protect small trees that have germinated naturally or resprouted from roots, prune them to promote growth of the apical meristem and, if necessary, set a stake to straighten the small tree. In Africa, natural regeneration has expanded *Acacia albida* from an original restricted range along rivers in Southern Africa to an extensive range that reaches across the continent north to the Sahel. Natural regeneration requires no external inputs. It concerns species well known and appreciated by rural people. It focuses on young trees that have demonstrated their hardiness by surviving with no human caretaker, no watering, and no special treatment. Natural regeneration not only augments the supply of wood, poles, fruit, medicine, and other forest products, it puts trees where farmers and herders need them – in fields to maintain soil fertility and in pastures to provide forage.

Photosynthetic activity converts only a fraction of total available solar radiation to wood. Nevertheless, the inefficiency of human tools for the conversion of wood to heat and light renders human end-uses even more wasteful. **Table 5** shows this energy chain from sunshine to wood end-use in the West African Sahel.

Improved cook stoves with higher fuel efficiencies can help conserve vegetative cover in rural areas that depend on firewood. In many areas, women customarily cook with a kettle over an open fire. International development agencies have helped to develop stoves such as, in Senegal, the *ban ak suuf*, a horseshoe-shaped hearth constructed from local clay that provides an enclosed combustion space that more effectively channels heat to the cooking vessel. The *lorena* in Guatemala is another improved efficiency earthen stove. The *jiko* in Kenya and *sakkanal* in

Senegal are enclosed metal or ceramic charcoal stoves that more effectively contain heat than traditional open charcoal burners.

For centuries, society has channeled water to mill grain and captured wind to move sailing ships and pump water. Small water and windmills comprise a form of traditional energy that generally requires only local materials and expertise for building and maintenance. The simplest water mills are run-of-the-river systems in which a water wheel is placed in the current of a perennial stream or river. A water wheel typically turns a circular stone for the grinding of grain. More advanced systems use water channels, pipes, Pelton wheels, or other devices to increase rotation speeds enough to turn a turbine to produce electricity. Small hydropower is most common in mountainous countries like Perú. The simplest windmills have a fan with wood or metal blades erected on a tower 5–15 m tall. The fan axis rotates on a horizontal axis, lifting a vertical rod connected to a plunger in a pipe well dug down to the water table. The movement of the plunger lifts water to the surface. This type of windmill is most common in flat grassland regions. Windmills in the Netherlands pumped water from extensive inundated areas that the Dutch enclosed with dikes, dried, and used for agriculture.

Future Energy Paths

Human energy use directly alters biodiversity through changes in land use and through industrial pollution. Indirectly, human energy use is altering biodiversity through the emission of greenhouse gases that cause global climate change and through other broad impacts on the natural function of ecosystems. Not only does the direct processing of energy generate environmental impacts, but the end-uses that convenient energy forms make possible produce impacts at all scales: individual species, local sites, landscapes, continents, and the world.

Table 6 summarizes the major environmental impacts of human energy use on biodiversity. **Table 7** summarizes the extensive land requirements and CO_2 production of energy sources. Land use change for energy use destroys and fragments natural ecosystems. Globally, climate change caused by emissions of CO_2 and other greenhouse gases constitutes the most severe impact of fossil fuels, but nonfossil fuel sources also produce air and water pollution. No energy transformation system operates without negative environmental impacts, yet renewable sources generally restrict harmful effects to the

Table 6 Major sources of biodiversity impacts from human energy use

<i>Impact</i>	<i>Oil</i>	<i>Natural gas</i>	<i>Coal</i>	<i>Nuclear fission</i>	<i>Hydroelectric</i>	<i>Renewable technologies</i>	<i>Wood</i>
Terrestrial habitat destruction and fragmentation	Exploration, access roads, pipelines	Exploration, access roads, pipelines	Mining, electricity transmission lines	Mining, electricity transmission lines	Inundation of vast land areas, changes to river hydrology	Land requirement for solar collectors, wind turbines, crops for biofuels	Destruction or fragmentation of habitat from unsustainable harvesting
Water pollution and damage to aquatic species	Oil spills, drilling muds, soil eroded from pipeline corridors and roads	Natural gas liquids spills, soil runoff from pipeline corridors and roads	Acid mine drainage, water removal for mining and plant cooling, entrainment, impingement, thermal pollution	Acid mine drainage, water removal for mining and plant cooling, entrainment, impingement, thermal pollution	Complete alteration of habitat, barriers to migration, entrainment, impingement, thermal changes, PCBs from transformers	Toxics from photovoltaic production, water removal for cleaning solar collectors and irrigating biofuel crops, pesticide and fertilizer from production of biofuels	Soil runoff from overharvested areas and roads
Air pollution	CO ₂ , toxic organic compounds from refining	CO ₂ , flaring, volatilization of CH ₄	CO ₂ , SO ₂	Radiation, toxic halogenated compounds in fuel processing		CO ₂ emissions from biofuels farm machinery	CO ₂ from burning
Solid waste	Oil spills, sludge	Natural gas liquids spills, sludge	Mine tailings, sludge	Radioactive waste	PCBs from transformers	Toxics from photovoltaic production	
Major end-uses	Automobiles	Cooking, heating	Electricity	Electricity	Electricity, smelters	Electricity	Cooking, heating

capital formation stage and do not produce much pollution from operations.

Environmental impact is equivalent to the multiplicative effect of population, affluence, and technology (Holdren and Ehlich, 1974):

$$\text{Environmental impact} = \text{Population} \times \frac{\text{Resource use}}{\text{Person}} \times \frac{\text{Environmental impact}}{\text{Resource use}}$$

Because the environmental impact of human energy use is proportional to the rate of energy use, and energy use is proportional to economic production, the IPAT (impact = population $\times$ affluence $\times$ technology) equation for energy becomes:

$$\begin{aligned} \text{Environmental impact} &\propto \text{Human energy use} \\ &= \text{Population} \times \frac{\text{Economic production}}{\text{Person}} \\ &\quad \times \frac{\text{Energy use}}{\text{Economic production}} \end{aligned}$$

Economic production per person, often expressed as dollar of GDP per person, indicates a society's level of material

Table 7 Land requirements and carbon dioxide emissions for electric generation

	<i>Land required (ha MW⁻¹)</i>	<i>CO₂ emissions (t GW⁻¹ h⁻¹)</i>
Coal	0.8–8.0	900
Oil	0.3–0.8	850
Natural gas turbine	0.3–0.8	560
Solar photovoltaics	3–7	50
Wood and other biomass	150–300	40
Solar thermal electric	1–4	40
Nuclear	0.8–1.0	30
Hydroelectric	2–1000	20

affluence, although GDP does not price ecosystem services such as clean water and natural habitat at their full value and values activities with negative impacts, such as military spending, as positive. Energy use per unit of economic production, expressed as watts per dollar of GDP, indicates a society's level of technological efficiency.

This relationship highlights the leverage of energy conservation and efficiency in reducing the environmental impact of energy use. Improvements in energy efficiency reduced the energy intensity of economic activity in the U.S. by nearly one-third between 1975 and 1995 (U.S. Department of Energy, 2010). Energy conservation and currently available efficiency improvements could substantially reduce industrial energy use and greenhouse gas emissions. Energy efficient vehicles and appliances, installation of insulation and other residential weatherization features, and simple changes in driving behavior such as slower acceleration and reduced highway speeds could reduce U.S. greenhouse gas emissions 7% (Dietz *et al.*, 2009). In addition to those conservation and efficiency actions, walking or using public transit instead of cars, substitution of renewable energy sources for nonrenewable sources, and other currently available improvements could meet global energy uses and stabilize greenhouse gas emissions by the mid-twenty-first century (Pacala and Socolow, 2004).

If the world does not adopt such improvements, the historical path of industrialization has only left costly and environmentally disruptive energy sources. The earliest exploitation of fossil fuels depleted the most convenient oil and gas deposits. This phenomenon explains why fossil fuel production over time follows the bell-shaped Hubbert Curve. Deposits are now more remote, deeper underground and underwater, and dispersed. Furthermore, low-cost energy has shaped the expectations of people around the world for inexpensive on-demand energy services. Societies subsidize the provision of convenient energy through infrastructure support to energy industries, tax breaks to oil drillers, preferential treatment to automobile companies, and other schemes.

Depletion of nonrenewable resources (Table 8) and other environmental and social constraints hobble most future energy options: oil and gas reserves will only last decades; coal burning releases the principal cause of global warming, CO₂;

Table 8 Remaining world energy reserves 2000

<i>Nonrenewable energy stocks</i>	<i>Reserve (TW year)</i>	<i>Time remaining at 2008 rates (years)</i>	<i>Carbon emissions (Gt)</i>
Uranium	80	80	20
Oil	220	40	1600
Natural gas	230	60	1100
Coal	1100	250	8600

<i>Renewable power flows</i>	<i>Potential (TW)</i>	<i>Time remaining</i>	<i>Carbon emissions (Gt year⁻¹)</i>

biomass energy requires vast amounts of land; a small number of exploitable sites limits the potential for hydroelectric and wind power; and health and safety problems prevent expansion of nuclear energy.

Although engineers have placed enormous effort into the development of technologies such as hydrogen cars, fuel cells, and nuclear fusion, exotic devices will not resolve our energy problems if they depend on nonrenewable fuels. Instead, energy efficiency, conservation, and renewable energy offer a sustainable future energy path for the world. For this path, the goal is not the acquisition of energy stocks and devices, but the provision of services and end-uses. In effect, we don't require light bulbs, we need illumination.

Glossary

Homonymy The same scientific name applied to two or more species.

Synonymy Two or more scientific names applied to the same species.

Significance

Responses to attempts to answer the question of how many extant species there are on Earth take a variety of forms. Some regard these attempts as meaningless exercises, given the lack of resolution of fundamental issues of the definition and recognition of species. Others find them futile, given the extraordinary difficulties in providing an accurate answer. More positively, some suggest that the question provides an important challenge to the state of understanding of global biodiversity, and that the attempts to answer it provide a valuable test of that understanding. Others go further, and argue that the answer is a basic fact that we should know, on a par perhaps with estimating the global quantities of the elements, the rate of drift of the continents, or the masses of atomic particles. Finally, some maintain that sound knowledge of global species richness will facilitate better answers to other important questions, such as the extent to which the carrying capacity of diversity on Earth has been attained, the rate at which species are becoming globally extinct, and the scale of the task faced by species conservation.

Fundamental Issues

Determining the number of species in an area is one of a general, and often difficult, set of problems in which an estimate of S is desired, where a statistical population, finite or infinite, is partitioned into S classes (Bunge and Fitzpatrick, 1993). A number of basic assumptions have typically to be made in such circumstances. These almost invariably become more problematic as the area concerned becomes larger, and thus particularly significant when attempting to estimate global species numbers.

First, the S classes should be defined in a consistent fashion. Unfortunately, this constitutes a major problem when estimating global species richness. For some higher taxa, known species (a sample s of S) have arguably been recognized on a reasonably uniform basis, usually employing a morphological species concept and definition. However, for other higher taxa, this basis has changed both as knowledge of key characters discriminating between species and as available technologies have developed, and as different species concepts (e.g., biological, ecological, morphological, and phylogenetic) have been favored. Moreover, for known species in different higher taxa, the same basic concept has been applied in different ways, or different species concepts have predominantly been applied.

Second in two samples, s_i of S , both the number of classes in common and the number unique to each sample i should be estimable. Whereas for better-known higher taxa, determining the overlap in species composition is a relatively trivial exercise, for others it is not. This is because of the huge challenge provided by the geographic variation exhibited in the traits of many species. The use of molecular approaches to species identification is reducing this problem, although this of course introduces a basis for species identification that differs from that which has been applied historically.

Third, S is assumed to remain constant. However, current species extinction rates have been estimated, and forthcoming rates predicted, to exceed the background rates recorded in the fossil record by orders of magnitude. Thus, an estimation of S is a moving target. Given the extremely rough and ready nature of most attempts to estimate global species richness, arguably this is not yet a major problem. However, if estimates were to become sufficiently refined, it could become so.

Fourth, the size of a sample s of S is commonly assumed to constitute a reasonable proportion of S . However, although across all higher taxa of eukaryotes, known species may constitute perhaps a fifth of the global number of extant species, it is quite possibly considerably less. Indeed, for some individual higher taxa, this figure is very much smaller. A typical large areal sample may contain hundreds or thousands of species, and thus fractions of a percent of global species richness.

Finally, it is commonly assumed that it is possible to take a sample s that is randomly drawn from S . Given the diversity of habitats and species (and the different challenges they pose for sampling), this is in practice impossible at a global scale.

Methods of Estimation

Counting

On the face of it, the best way of finding out how many species (S) there are would simply be to count them. However, other issues aside, the diversity of life is so great that at a global scale this presents a truly formidable task, and one that has never risen sufficiently high on the agenda of humankind to be given serious consideration. Nonetheless, the question of how insurmountable the obstacle would be if substantial resources, technology, and ingenuity were brought to bear remains unanswered. Some believe that it is attainable in a matter of decades, but others are unconvinced. For a small number of species-poor higher taxa, reasonable estimates of global richness have indeed been obtained simply

by counting. However, in few cases, are these estimates likely to be definitive. Even for the better-known groups, new species continue to be discovered every year (e.g., birds and mammals), and the boundaries between species continue to be revised. Even when all the extant species in a group have been encountered, lists of described species are prone to two kinds of errors. First, the same species name may have been attributed to more than one species, so-called homonymy. Second, more than one species name may have been attributed to the same species, so-called synonymy. The balance of these two kinds of errors leans strongly toward synonymy, with many thousands of species names thought to be synonyms. Indeed, the actual level of synonymy has proven to be a key issue in, for example, attempts to determine the global species richness of plants, a group for which surprising uncertainty and disagreement exists around such estimates. Here, the highly variable synonymy rate among different groups of plants that have been well studied in this regard makes the assessment of the overall level of synonymy across all the known species difficult.

Canvassing Experts

Rather than take lists of described species at face value, estimates of overall species richness can potentially be improved based on the opinions of those taxonomic experts who have studied the relevant groups over long periods, and have gained an understanding of the frequency with which new species are encountered and described, of the levels of homonymy and synonymy in species lists that have been recognized but remain unresolved (their formal resolution is time consuming and is not presently a high priority in systematic studies of many groups), and of likely hidden levels of homonymy and synonymy (Gaston, 1991). Indeed, many informal estimates of the richness of particular higher taxa have effectively been generated in this fashion. This approach to estimation makes the entirely untestable assumption that the experts know the taxonomic groups they investigate sufficiently well to make reliable estimates. At the very least, it seems likely that such estimates will be of rather variable accuracy. They may also suffer from systematic biases. The more speciose and geographically widespread the taxon the greater these problems are likely to be.

Temporal Patterns of Species Description

Overall numbers of species in some groups have been estimated by extrapolating to infinite time the growth in the cumulative numbers of taxonomically described species through time ($S = f(s(t))$, where t is time). This assumes that temporal patterns of species description follow some relatively simple pattern (much debate surrounds the most appropriate model, although the pattern is commonly assumed to be approximately sigmoidal, with low early and late rates of description separated by a period of rapid increase), and that this pattern can be identified. Unfortunately, for the majority of higher taxa, relatively small proportions of species have been described, and insufficient information is available in the temporal patterns of description of those species to provide any

indication as to what might be an appropriate model on which basis to predict the future history of descriptions. Moreover, temporal patterns of description often tend to be highly idiosyncratic. This is because they can be profoundly influenced by individual taxonomists (a high proportion of species in a group are formally described by a relatively small number of taxonomists), by changes in spatial patterns of collecting effort (which are shaped by opportunity as well as biological considerations), by changes in the features by which species are distinguished or the species concept employed, by the development or application of new technologies which facilitate or enable those changes, and by funding possibilities (description of species in some groups has at various times collapsed through lack of support). Indeed, these issues have meant that estimates of the number of species remaining to be discovered even in rather well-known taxonomic groups generated using temporal patterns of species description have sometimes quickly proven wildly inaccurate.

Proportions of Undescribed Species

An alternative approach to estimating global species richness is to determine the ratio of previously unknown to previously known species in large samples of specimens, and then to extrapolate from the overall numbers of known species (i.e., $S = S_K(s_i/s_k)$, where S is the total number of extant species, S_K the number of those that were previously known, s_i the total number of species in a sample, and s_k the number of species in the sample that were previously known). This assumes that the samples are representative. However, unfortunately, in practice samples tend to be much more serendipitous, and biased both in space and by higher taxon. Species from temperate regions tend to be much better sampled than are those from tropical and megadiverse regions, as are those that, on average, are larger bodied, more abundant (locally or regionally), more widely distributed, occupy a larger number of habitats or life zones, or are economically more important (e.g., of agricultural or medical significance). Nonetheless, arguably, this approach toward estimating overall global species richness or that of major higher taxa has not been sufficiently exploited, and coupled with a carefully designed sampling program could go far toward improving those estimates, if it were sufficiently well resourced.

Extrapolating From Well-Studied Areas

Overall, numbers of species globally or in very large regions have been estimated by extrapolating from those, typically rather small, areas for which numbers of species are reasonably well known, usually exploiting a species–area relationship ($S = f(s(A))$, where A is area). This assumes that the areas for which overall species numbers are better known are representative of those for which they are not. Of course this is not so, with the former being predominantly temperate and with well-developed infrastructures. The method also assumes that the form of the species–area relationship is sufficiently well established and that area is a sufficient predictor of the numbers of species present in a region. A major complication

is that over a wide span of variation in area the species–area relationship is complex, with a slope that varies between small areas and large ones, and commonly characterized as tri-phasic. Ways of estimating the slope at large areas from that at small ones have been explored, based on the change in similarity of species composition among small areas with increases in the distance by which they are separated. Extrapolation from well-studied areas is of limited value in estimating overall global species richness because for no area in the world has species composition of all groups been entirely inventoried.

Extrapolating From Well-Studied Groups

This involves estimating overall numbers of species based on the global numbers in well-known groups and estimates of the ratio of the numbers of species in these groups to others in those, typically few, regions where the latter are reasonably well known (i.e., $S_A = S_B(s_a/s_b)$, where S_A is the total number of extant species in the less well-known group, S_B the total number of extant species in the better-known group, s_a the number of species of the former group in the well-known region, and s_b of the second group). This assumes that these ratios of numbers of species in well-known and other groups remain reasonably constant across space. This is usually not the case. Thus, although this approach has played an important role in estimates of global species richness, those estimates have large associated uncertainties.

Species–Abundance Distributions

If reasonable estimates can be made of the global numbers of individuals of a higher taxon, and the shape of the species–abundance distribution (the frequency of species with different numbers of individuals) can be assumed ($S = f(s(N))$, where N is abundance), then the global numbers of species can be estimated. Such an approach has particularly been employed in attempts to estimate the species richness of microbes, for which the numbers of individuals are plainly enormous, and has provided useful insights into their diversity (Curtis *et al.*, 2002). A lognormal species–abundance distribution tends to be assumed, although it is well established that species–abundance distributions cannot be strictly lognormal.

Species–Body Size Distributions

In general, a much higher proportion of large-bodied species are known to science than small-bodied. If the overall shape of the species–body size distribution (the frequency of species of different body sizes) of all species, or a major component thereof, could be simply characterized ($S = f(s(M))$, where M is body size), then one could extrapolate from the known part of this distribution (that for the larger species) to the unknown part (that for the smaller species) to estimate total species numbers (May, 1988). The obvious difficulty here lies in knowing the shape of the regional or global species–body size function, and the extent to which this is approximated by that of species–body size distributions from smaller areas.

Such limitations have largely thwarted effective use of this approach to date.

Trophic relations

If the numbers of species of a taxonomic group consuming a particular kind of resource can be determined, and their level of specialism to that resource and the number of kinds of resources are known, the number of species of the group can be estimated. Such an approach provided the starting point for Erwin's (1982) dramatic, and much cited, upward revision of the estimated global numbers of arthropod species. The debate that this engendered centered foremost on the assumed level of specialism, in this case the specificity of tropical beetle species to particular tree species, which can be hard to determine in systems with large numbers of resource types, but has a powerful influence on the resultant estimates. In this instance, subsequent detailed studies have generally served to suggest lower levels of specialism (or increased levels of generalism) than those originally assumed.

Current Estimates

More or less formally, various combinations of these approaches have been used to provide assessments of how many extant species there are globally in large taxonomic groups and, by summation of these estimates, how many extant species there are overall. Inevitably, given the previous remarks, some of these estimates are highly speculative, and all will be subjected to further (typically marked) revision. One recent summary for eukaryotes is provided in Table 1. The working figure for overall numbers is around 10 million species, an estimate with which many workers seem broadly comfortable.

The particular pattern of change in global species richness since the emergence of life 4–3.5 billion years ago remains contentious. However, it is plain that there has been a dramatic net increase. If more than 98% of species are now extinct, then based on estimates of numbers of extant species, and accepting that the error in such a calculation is likely to be substantial, 500 million eukaryote species may have ever lived.

The Greatest Uncertainties

The greatest uncertainties in estimates of global species richness lie in understanding the biodiversity associated with a relatively limited number of kinds of environments and of higher taxa.

Environments

Tropical Forest Canopies

Despite their large extent (> 11 million km²), tropical forest canopies long remained poorly explored. This has changed through the application of a variety of techniques that have much improved access to a previously largely inaccessible environment (e.g., rope-climbing techniques, aerial walkways,

Table 1 Estimates (in thousands), by different taxonomic groups, of the global numbers of extant eukaryote species that have been described and overall. Substantial uncertainty is associated with most of these figures (see text)

	<i>Described species</i>	<i>Overall species</i>	<i>Accuracy of overall species estimate</i>
Protoctista	29	1000	Very poor
Plants	310	391	Good
Fungi	99	1500	Moderate
Nematodes	25	500	Very poor
Arthropods	1176	5892	Moderate
Mollusks	85	200	Moderate
Chordates	65	81	Good
Others	101	364	Moderate
Total	1890	9928

cranes, and balloons). This has revealed much higher levels of richness of some groups than had been anticipated, and lower richness of others, but overall has served to confirm the significance of tropical forests for global species numbers.

Soils

Despite the much greater ease of access, understanding of the species richness of soils has been severely hampered by the small body size of many of the associated species, and the poor efficiency of many extraction methods. Detailed studies of soils at a single site in the Scottish borders generated high species richness estimates, particularly among small organisms, with 500–5000 bacteria, 365 protozoa, and 400–500 nematodes (Fitter *et al.*, 2005). Spatial turnover in species composition remains poorly explored, so the basis for estimations of regional or global species richness and patterns is largely lacking.

Deep Ocean

Areas at depths below 1 km in the oceans cover more than half of the planet, and the associated biodiversity remains one of the great imponderables. As with tropical forest canopies, gaining better access is important for improving this situation, as to date samples have been obtained from only a miniscule proportion of this extent. Thus, alongside developments in remotely operated vehicles, bottom landers, submarines, sonar, and video, for example, the identification of new kinds of communities of organisms, such as hydrothermal vents, cold seeps, and cold-water coral reefs, has occurred. Studies on the fauna of deep-sea floors in the Atlantic and Pacific uncovered a high level of species richness, leading to suggestions that there may be 10 million species in the deep sea (Grassle and Maciolek, 1992). Although this seems likely to be a marked overestimate, it is undoubtedly the case that large numbers remain to be discovered.

Coral Reefs

In contrast to tropical forests, soils, and the deep ocean, the global area covered by coral reefs is only about 600,000 km² (ca. 0.18% of total area of oceans). Nonetheless, it has been estimated that up to one quarter of all marine species and one-fifth of known marine fish species live in coral reef ecosystems,

leading it to be seen as the marine equivalent of tropical forests.

Higher Taxa

Viruses

If one accepts that they exhibit at least some of the primary features common to all life forms, then the numbers of species of viruses are likely to constitute a significant issue in determining global species numbers. Most forms of life have some sort of susceptibility to viruses, they may exhibit significant levels of host specificity, and many types of viruses are known from some hosts. Moreover, previously unknown assemblages and types of virus are currently being found on a massive scale. However, what constitutes a species of virus, and the comparability of any species concept with those applied to other groups of organisms, are difficult issues. At present, it seems unlikely that these could be satisfactorily resolved, particularly given evidence that many viruses may be continually and randomly recombining with DNA that they encounter.

Bacteria

Basic understanding of the number of species of bacteria (and archaea) is complicated by frequent difficulties in applying standard species concepts to these creatures (resort is usually made to operational taxonomic units (OTUs)), by the difficulty of culturing the vast majority of them and thereby applying classical identification techniques, and by the unimaginable numbers of individuals that exist. The numbers of species estimated to occur in even very small areas can vary by several orders of magnitude, depending on the approach taken to estimation. Use of DNA reassociation techniques has revealed that in pristine soils and sediments with high organic content, samples of 30–100 cm³ correspond to ca. 3000–11,000 different genomes, and may contain 10,000 different prokaryotic species of equivalent abundances (Torsvik *et al.*, 2002). Globally, the diversity of bacteria, both in terrestrial and marine systems, may be far larger than many had previously imagined, and has been argued to comprise possibly millions of species, and by some many orders of

magnitude more than that. If this is correct, then the vast majority of microbial diversity remains unexplored and undocumented.

Protozoa

A critical issue in understanding the extent of microbial diversity, whether it be bacterial or protist, is the extent to which individual microbial species are cosmopolitan in their distribution. In particular, it has been argued that driven by huge population sizes microbes are able to disperse widely and so occur wherever their habitat requirements are met, resulting in high local richness but relatively low global richness (Finlay, 2002). The evidence that this is so for protists, and thus how large is their global richness, is contentious. The debate rests heavily on how well morphological features (which have long been used in protist taxonomy) serve to discriminate among species, the interpretation of observed patterns of genetic variation, and the extent to which documented examples of apparently locally endemic species are products of undersampling.

Fungi

Somewhat in contrast to microbes, the high local species richness that has been documented at some sites for fungi has been argued to provide evidence for their high global species numbers. A working global estimate of 1.5 million species of fungi, based primarily on extrapolation from temperate studies, has been widely cited (Hawksworth, 2001). On the one hand, some tropical studies and some of endophytic species suggest that this may constitute a substantial underestimate. On the other hand, it has been argued that the frequency of discovery of previously unknown species in areas whose fungi are not well studied suggests that the figure may be a substantial overestimate.

Nematodes

The local densities of individual nematodes can be extraordinarily high, and they are extremely widespread. However, how this vast abundance translates into numbers of species remains unclear. Figures of 1–100 million extant species have been suggested. But recent analyses have cast severe doubt on the more extreme upper estimates (Lambshead and Boucher, 2003). For example, suggestions of immense numbers of species in the deep sea have been challenged by data from the equatorial central Pacific, which suggest richness values more akin to those of moderately speciose coastal offshore regions.

Arthropods

Estimates of the global number of arthropods have ranged particularly widely. Much of the uncertainty rests on the numbers of species that are to be found in the tropical rain forest canopy, the proportion that are restricted to this environment, and the degree of host specificity of herbivorous species in such forests (Novotny *et al.*, 2006; Hamilton *et al.*, 2010). Estimates have tended to fall as evidence has accrued that both restriction of species to the canopy and their host specificity tend to be lower than was previously assumed.

Among those higher taxa about which uncertainty in species numbers contributes most to uncertainty in overall global species richness, many, if not all, of their species are parasites, exploiting free-living organisms or other parasites for their resources. This has led to a lively debate as to whether parasitism is the most common lifestyle on Earth, and whether the majority of species are parasitic rather than free-living.

Prospect

If the past is anything to go by, long into the future prevailing estimates of global species richness will continue periodically to be revisited, as fresh data and improved methodologies become available. This is a healthy, albeit frustrating, comment on understanding of the magnitude of life on Earth.

Glossary

Biodiversity (or biological diversity) The full diversity of life on Earth, at all levels of biological organization, from molecules to genes, to populations, to species, and to ecosystems. It is a multidimensional concept difficult to measure, and in practice most focus is on diversity at the species level.

Biogeographic regions Large regions with characteristic assemblages of natural communities and species, distinct from other regions. There are several classifications of biogeographic regions, for example, into ecoregions and ecozones.

Endemic A species is said to be endemic to a given area when it cannot be found anywhere else. An area of high endemism may either have high numbers of species that only exist there or high concentrations of species with small ranges.

Irreplaceability The irreplaceability of a region is the degree to which that region is necessary as part of a

comprehensive conservation strategy. A region with high levels of endemism has high irreplaceability because it cannot be replaced by others if the endemic species are to be conserved.

Threatened species Species at risk, either of global extinction (globally threatened species) or of extirpation within a given region or country (regionally or nationally threatened species). The most authoritative reference for the identification of globally threatened species is the International Union for Nature Conservation (IUCN) Red List of Threatened Species. It distinguishes three categories of threat (in increasing order of risk): Vulnerable, Endangered and Critically Endangered.

Web of Science An online academic citation index provided by Thomson Reuters. It provides access to a diversity of databases of peer-reviewed scientific publications, which can be searched using multiple criteria (for example, particular keywords within particular years).

Introduction

The term “hotspot” is commonly used in science – as well as in everyday life – to refer to areas of high activity in, or importance to, something. In science, it is used in genetics (e.g., “recombination hotspots”; Smagulova *et al.*, 2011), geophysics (e.g., “hotspot volcanism”; Hieronymus and Bercovici, 2001), and in environmental sciences (e.g., “pollution hotspots”; Spiteri *et al.*, 2005). Within ecology, there are, for example, hotspots of population abundance (e.g., Nur *et al.*, 2011), of animal activity (e.g., Okkonen *et al.*, 2011), and of disease emergence (e.g., Caron *et al.*, 2011).

The term “biodiversity hotspots” refers to areas of high concentration of biodiversity and/or high conservation value. Within this general meaning, multiple definitions have emerged, with different conceptual and practical implications. The term is now widely used in the biodiversity conservation literature (e.g., a Web of Science search for “biodiversity AND hotspot” yields over 2000 citations), but, perhaps because it seems so intuitive, it is frequently used without being defined, its multiple meanings are often confused, and the resulting literature is replete with ambiguity and misunderstandings. This article reviews and clarifies the definition, history, usage and impact of, and criticism toward, the various concepts of biodiversity hotspots.

Different types of Biodiversity Hotspots

Two main versions of the concept of biodiversity hotspots have become particularly influential in conservation theory

and practice. One (referred throughout as “biodiversity hotspots *sensu* Myers/Conservation International (CI)”) corresponds to large biogeographic regions that have exceptional levels of plant endemism (>1500 plant species as endemics) and exceptional levels of threat (have lost more than 70% of their original vegetation cover) (Myers *et al.*, 2000, 2001). These correspond to very specific areas of the planet, even if their number and precise boundaries have been evolving over time. This concept has been extended to marine systems to identify regions of exceptional levels of endemism and of threat in tropical reefs (Roberts *et al.*, 2002).

The second main usage of biodiversity hotspots corresponds to areas with particularly high numbers of species (designated below as “biodiversity hotspots *sensu lato*”). Rather than referring to specific areas, this concept is associated with a methodology for highlighting sites of conservation interest within a given study region, and for a given taxonomic group. It was first used to refer to the top 5% sites in Britain with the highest richness in plant and animal species (Prendergast *et al.*, 1993), but has subsequently been extended, for example, to highlight areas with high concentrations of rare (Williams *et al.*, 1996) or threatened species (Dobson *et al.*, 1997), of a diversity of taxonomic groups, at various spatial scales, and following multiple variations on the precise method for selecting the top sites.

Biodiversity Hotspots *sensu* Myers/CI

Myers first proposed the concept of biodiversity hotspots in 1988 (Myers, 1988), defining them as regions that both feature

Figure 1 The temporal evolution of the spatial coverage of the biodiversity hotspots *sensu* Myers/Conservation International: (a) in 1988 (red; adapted from Myers (1988) Threatened biotas: “hot spots” in tropical forests. *Environmentalist* 8: 187–208, with permission from University of Chicago Press); and in 1990 (purple; adapted from Myers (1990) The biodiversity challenge: Expanded hot-spots analysis. *Environmentalist* 10: 243–256, with permission from University of Chicago Press); (b) in 1999–2000 (adapted with permission from Mittermeier RA, Meyers N, Robles Gil P, and Mittermeier CG (1999) *Hotspots – Earth’s Biologically Richest and Most Endangered Terrestrial Ecoregions*. Chicago, USA: CEMEX/Conservation International and the University of Chicago Press; and Myers N, Mittermeier RA, Mittermeier CG, Fonseca, GAB, and Kent J (2000) Biodiversity hotspots for conservation priorities. *Nature* 403: 853–858); and (c) in 2004 (adapted with permission from Mittermeier RA, Robles Gil P, Hoffmann M, *et al.* (2004) *Hotspots Revisited: Earth’s Biologically Richest and Most Endangered Terrestrial Ecoregions*. Mexico City, Mexico: CEMEX, Conservation International and Agrupación Sierra Madre). In (a) and (b) the red lines correspond to the outer limits of the Hotspots, encompassing groups of islands.

exceptional concentrations of species with exceptional levels of endemism, and that face exceptional degrees of threat (Figures 1(a) and 2). Although no thresholds were proposed then for defining exceptional endemism or threat, Myers made it clear that it was the spatial coincidence of these two criteria (and not just one or the other) that made hotspots global conservation

priorities for preventing species extinctions. He focused on vascular plant endemism, but predicted these areas would also capture disproportional fractions of global animal diversity, and he evaluated threat as the fraction of original forest estimated to have been lost from each region. The 1988 paper identified 10 tropical forest hotspots (Myers, 1988), complemented 2 years

Figure 2 The temporal evolution of the list of biodiversity hotspots *sensu* Myers/CI (thick arrows, strong correspondence; thin arrows, major change in boundaries). Key statistics are presented for each of the 34 Hotspots in the 2004 version. Reproduced with permission from Mittermeier RA, Robles Gil P, Hoffmann M, *et al.* (2004) *Hotspots Revisited: Earth's Biologically Richest and Most Endangered Terrestrial Ecoregions*. Mexico City, Mexico: CEMEX, Conservation International and Agrupación Sierra Madre.

later by eight additional areas, four in tropical forests, and four in mediterranean biomes (Myers, 1990; Figures 1(a) and 2).

In 1989, the concept of biodiversity hotspots was embraced by CI, the US-based nongovernmental international conservation organization (Mittermeier *et al.*, 1999). In collaboration with Myers, CI scientists refined the criteria for identifying hotspots by establishing quantitative thresholds for endemism (at least 0.5% or 1500 of the world's 300,000 vascular plant species) and for threat (loss of at least 70% of the primary vegetation). CI placed hotspots at the core of their global conservation strategy, complemented by High Biodiversity Wilderness Areas (what Myers had called "good news areas"; Myers, 1988) – regions of similarly high levels of plant endemism (> 1500 plant species) but with most of their original vegetation still intact (< 30% lost) (Mittermeier *et al.*, 1998, 2002, 2003b). A revised set of 24 hotspots was proposed in 1998 (Mittermeier *et al.*, 1998), immediately increased to 25 (Mittermeier *et al.*, 1999; Myers *et al.*, 2000, 2001) (Figures 1(b) and 2). These 25 hotspots were estimated to hold 44% of all species of vascular plants and 35% of all species of terrestrial vertebrates as endemics. Their total area corresponded to 11.8% of the Earth's land surface, but their

remaining original vegetation was estimated to occupy only 1.4% of the planet. Myers *et al.* (2000) advocated focusing conservation efforts on these 1.4%, as a "silver bullet" strategy to prevent species extinctions worldwide. This strategy recognizes that such concentrations of endemic species in hotspots are a conservation opportunity, but they also reflect a very high jeopardy: a large fraction of global plant diversity is potentially at risk of extinction by being restricted to regions that have high levels of threat.

The latest list of 34 biodiversity hotspots was published in a 2004 revision (Mittermeier *et al.*, 2004) (Figures 1(c), and 2). The quantitative criteria remained the same, but improved data on plant endemism and on habitat loss revealed six previously overlooked areas. Boundaries were redefined in order to align hotspots with groups of ecoregions (large biogeographic units with distinct assemblages of species and communities; Olson *et al.*, 2001), resulting in two of the 1999–2000 hotspots being split. More worryingly, one region (East Melanesia) was identified as a newly formed hotspot: despite being considered part of a Wilderness Area in 1998 (Mittermeier *et al.*, 1998), it was found to have lost 70% of its natural forest by 2004. Overall, the 34 hotspots correspond to

15.7% of the global land surface, their original habitat covering only 2.3%. Between them, they are estimated to hold at least 150,000 plant species as endemics (50% of the world's total), and an overall 22,022 terrestrial vertebrate species (77% of the world's total) including 11,980 species as endemics (42% of the world's total).

The list of biodiversity hotspots *sensu* Myers/CI is therefore dynamic, and additional updates are expected as knowledge improves on the distribution of species and on habitat loss, and as land use changes worldwide. The 2004 update highlighted two regions (Queensland Wet Tropics and Taiwan) that came close to meeting the hotspots criteria, and mentioned three others (Angola Escarpment, rainforests of eastern Australia, and southeastern China) likely to be considered in future revisions (Mittermeier *et al.*, 2004).

Roberts *et al.* (2002) extended the concept of biodiversity hotspots *sensu* Myers/CI to marine systems, by identifying areas of high levels of endemism and of high threat across the world's tropical reefs. Using data on the distribution of 3235 species of reef fish, corals, snails, and lobsters, they mapped species endemism across a 50,000 km² degree grid by calculating the sum in each cell of the reciprocal of the range size of each species. They then identified 18 multitaxa centers of endemism from areas that were in the top 10% of the cells for at least two taxa. Finally, 10 of these regions considered under high threat were identified as marine biodiversity hotspots. Threat was assessed using a map-based indicator of risk to coral reefs from coastal development, marine pollution, overexploitation, and inland pollution (Bryant *et al.*, 1998).

Biodiversity Hotspots *sensu lato*

The concept of biodiversity hotspots as areas with high concentration of species was (possibly) first proposed by Prendergast *et al.* (1993) (who cited Myers (1988) as the source for the term, but then used it in a different sense). Their analysis was based on the distribution of butterflies, dragonflies, aquatic plants, breeding birds, and liverworts in Britain, and hotspots were defined as the top 5% cells (10 km²) with the highest species richness for each taxon. Later in that same year, Pomeroy (1993) independently applied the term hotspots to refer to African countries with a high diversity in plant species, after controlling for variation in country area using the species–area relationship.

The concept of hotspots was extended to areas with high concentrations of rare species by Williams *et al.* (1996), who distinguished between “richness hotspots” (the top 5% sites in terms of diversity) and “rarity hotspots” (the top 5% sites in richness of rare species, defined as the 25% species with the smallest ranges). BirdLife International's Endemic Bird Areas are a global application of the concept of rarity hotspots: there are 218 regions where the distributions of two or more restricted-range bird species (with ranges smaller than 50,000 km²) overlap (Stattersfield *et al.*, 1998).

The concept of hotspots was further extended to refer to concentrations of threatened species (Dobson *et al.*, 1997), dubbed elsewhere as “threatspots” (Troumbis and Dimitrakopoulos, 1998). The term hotspots has since become a common way of designating areas with high richness of all, rare, or threatened species, either in absolute terms (Orme

et al., 2005; Ceballos and Ehrlich, 2006; Grenyer *et al.*, 2006), or after controlling for variation in the area of the analyzed units (e.g., Veech, 2000; Guilhaumon *et al.*, 2008).

The concept of hotspot continues to expand as it is applied to other facets of biodiversity, for example, through the designation of hotspots of functional diversity (Lucifora *et al.*, 2011), or hotspots of beta diversity (Harborne *et al.*, 2006). There is however one key aspect in which hotspots *sensu lato* remain conceptually distinct from hotspots *sensu* Myers/CI: the former apply to peaks of diversity along a particular axis of diversity or of threat, whereas the latter highlights areas that have both high endemism and high threat. The two approaches can meet if hotspots *sensu lato* are defined as concentrations of species that are simultaneously threatened and spatially rare.

Biodiversity Hotspots in the Literature

A review of the usage of the term “biodiversity hotspots” in scientific journals illustrates how the various concepts have permeated the literature. A Web of Science search (June 2011) for publications on biodiversity and hotspots (search term: Topic=((hotspot* OR hot-spot* OR hot spot*) AND biodiversity) in four journals (three high impact journals, *Nature*, *Science*, and *Proceedings of the National Academy of Sciences USA*; and the highest impact journal on biodiversity conservation, *Conservation Biology*) yielded 180 articles. Of these, 23 were excluded: 17 for not using the term “hotspot” at all; four for being news articles without references; and two for using the term in a different sense from biodiversity hotspots (pollution hotspots, Grimm *et al.*, 2008; groundwater recharge hotspots, Herbert *et al.*, 2010). The remaining 157 articles were analyzed. Testifying the extent to which it has become a glamorous concept in the literature, a third of these articles (51/157) used the term hotspots in the title. The concept was used in four (partially overlapping) main ways (Figure 3): hotspots *sensu* Myers/CI; hotspots *sensu lato*; following other definitions; and without being defined. These are discussed below.

Biodiversity Hotspots *sensu* Myers/CI

The concept of biodiversity hotspots *sensu* Myers/CI has had substantial impact in the scientific literature. Indeed, the 2000 *Nature* paper (Myers *et al.*, 2000, now with over 3500 citations) is not only the most cited publication on biodiversity hotspots (Figure 4), but also one of the most cited studies in *Ecology* (was the most cited paper in *Environment and Ecology* in the 1998–2008 period; Thomson Reuters (2008)). Analysis of a sample of articles provides a deeper perspective of the way in which the concept of hotspots *sensu* Myers/CI has permeated the literature (Figure 3). Out of 157 articles analyzed, 99 (63%) used the term hotspots in this sense, including 88 who use it exclusively in this way. The dominant usage (2 in 5 of the 99 papers) was to highlight the value of the paper's study area as a global biodiversity hotspot (e.g., Bossuyt *et al.* (2004) and Delibes-Mateos *et al.* (2008)). Conversely, in a separate search for conservation articles focusing on five regions classified as biodiversity hotspots *sensu* Myers/CI, more than half

Figure 3 A review of the multiple uses of the term “hotspot” in the biodiversity literature. Data were obtained from a sample of 157 articles on biodiversity and hotspots, published in *Nature*, *Science*, *Proceedings of the National Academy of Sciences USA*, and *Conservation Biology*. They were classified into four (partially overlapping) main groups: those that use the term hotspots *sensu* Myers/CI; those that use it *sensu lato*; those that used it another way; and those that used it in an undefined way. The 99 papers on hotspots *sensu* Myers/CI were further classified into studies on marine hotspots (Roberts *et al.*, 2002) and studies on terrestrial hotspots, with the latter divided into: studies where hotspots themselves were units or subjects of analysis; papers whose study area was within a specific hotspot, this fact being mentioned as evidence of the relevancy of the study to global biodiversity conservation; papers where results were compared to hotspots; and papers where hotspots are mentioned as context. The 51 studies on hotspots *sensu lato* were split into those where the concept is mentioned merely as context, and those where analyses are done to identify hotspots of richness, of rarity, or of threat (or combinations of these three types).

Figure 4 Number of peer-reviewed papers on biodiversity hotspots according to whether they cite Myers *et al.* (2000; blue), or Prendergast *et al.* (1993; red), both (yellow), or none (green). Papers were found through Web of Science using the search term topic=(biodiversity AND hotspot*) (June 2011).

of the papers highlighted the global importance of their study areas by referring to the hotspot designation (Web of Science search for Topic=(“Atlantic Forest” OR Cerrado OR Madagascar OR Philippines OR “Western Ghats”) AND Publication Name=Conservation Biology; September 2011; 63 references found, of which 27 had one of the five hotspots as a study-area,

of which 15 refer to their study area as a biodiversity hotspot *sensu* Myers/CI). This suggests the concept of global biodiversity hotspots *sensu* Myers/CI has been widely embraced by conservation scientists working in these regions.

The second main usage of the concept of hotspots *sensu* Myers/CI (25/99) was in studies that focused on the hotspots themselves, either as spatial units or as subjects of analysis (Figure 3), for example, by comparing hotspots to other global conservation priorities (Brooks *et al.*, 2002), by quantifying the human impact on the hotspots (Cincotta *et al.*, 2000), or by investigating the degree to which hotspots represent evolutionary history (Sechrest *et al.*, 2002). In a sizeable fraction of papers using the concept of hotspots *sensu* Myers/CI (14/99), the study’s results were compared to hotspots, sometimes as a particular analysis, others as part of the discussion (e.g., Cardillo *et al.*, 2006 compared their predictions of future areas of high extinction risk with Myers/CI biodiversity hotspots), whereas in other publications (18/99) hotspots were mentioned to provide context, typically in the introduction (e.g., Lamoreux *et al.*, 2006 mentions hotspots as one approach that is based on ecoregions as spatial units). Finally, a few (4/99) studies focused on marine hotspots *sensu* Roberts *et al.* (2002).

Biodiversity Hotspots *sensu lato*

Although usage of the term hotspots *sensu* Myers/CI was tightly linked to the respective scientific publications (in 92/99 cases), only 21 out of 51 studies that used the concept of hotspots *sensu lato* quoted Prendergast (1993). And yet, most studies undertook analyses in Prendergast’s original sense of

peaks of species richness (29/51), with hotspots of rarity and of threat analyzed, respectively, in 10/51 and 7/51 of studies (Figure 3). This approach has been applied to a variety of taxa (e.g., moths, Grand *et al.*, 2004; beetles, Fattorini, 2006), of regions (e.g., South Africa, Maddock and Benn, 2000; Borneo, Meijaard and Nijman, 2003), and of spatial scales (e.g., from 2 km² landscapes, Gjerde *et al.*, 2004; to global, Orme *et al.*, 2005). The exact method for identifying the hotspots has also varied, including changes in the thresholds (e.g., the 10% top cells rather than the 5%; Maddock and Benn, 2000) and correction for area when the spatial units vary in size (e.g., Fattorini, 2006).

The other dominant usage of the concept of hotspots *sensu lato* (18/51) was in providing context, for example, by designating concentrations of species as hotspots (e.g., Mace *et al.*, 2003 referred to the description of 140 new amphibian species from Sri Lanka as “a new hotspot of diversity”) or by describing results from previous studies (e.g., Lawler *et al.*, 2003 mentioning the lack of hotspot congruence across taxa found by Prendergast).

Other Concepts of Biodiversity Hotspots

A small, but nonnegligible, fraction of the studies analyzed (15/157) proposed other concepts of biodiversity hotspots (Figure 3). A third of these (5/157) corresponded to “complementarity hotspots” (perhaps first coined by Araujo and Williams, 2001). These are sets of sites with a complementary species composition, selected not for their exceptional species richness as individual sites, but because together they maximize species representation (Margules and Pressey, 2000). However, this usage of the hotspots term is very unusual within the large literature on complementary reserve selection (see Hotspots and Systematic Conservation Planning).

The other concepts of biodiversity hotspots were: areas predicted to concentrate future species extinctions (“latency hotspots”; Cardillo *et al.*, 2006); sites of high environmental diversity (“environmental hotspots”; Chen, 2009); areas of active deforestation (“forest clearing hotspots”; Hansen *et al.*, 2008); areas of high vulnerability to traditional livelihoods are where agroecological systems and knowledge are threatened (“rural hotspots”; Harvey *et al.*, 2008); areas of high population abundance (Winston and Angermeier, 1995); areas where biodiversity is being generated (“evolutionary hotspots of diversification”; Petit *et al.*, 2003); areas of intense reciprocal selection (“coevolutionary hotspots”; Thompson and Cunningham, 2002); and areas of intense conservation activity (“conservation planning hotspots”; Reyers *et al.*, 2010).

Ambiguity in Usage

More than one in four of the 157 studies analyzed applied the term “hotspots” ambiguously. There were three main sources of ambiguity: the term “hotspot” was simply left undefined (in 13/157 studies; e.g., Lindenmayer and Hunter, 2010); the term was used to refer to multiple concepts without clarifying the differences (24/157; e.g., Orme *et al.*, 2005 used hotspots in both *sensu* Myers/CI and *sensu lato*, but treated them as equivalent); or the concept was defined and a reference provided, but the

two did not match (5/157; e.g., Bellwood *et al.*, 2004 defines hotspots as “areas of exceptional species richness” while citing Myers *et al.*, 2002).

Ambiguity has been prevalent in the hotspots literature since its early days, starting with Prendergast *et al.* (1993), who credited Myers (1988) for the term “hotspots” while defining them as “species-rich areas”. Unfortunately, this ambiguity has been at the root of substantial confusion, particularly when discussing the value and adequacy of hotspots as tools in conservation planning and action.

Biodiversity Hotspots in Conservation Planning and Action

Hotspots and Systematic Conservation Planning

The two main concepts of hotspots are closely intertwined – but in very different ways – with the broader literature on the selection of priority areas for conservation. This literature has expanded substantially since the 1980s, as the field of systematic conservation planning emerged in response to the recognition that the limited resources available to conservation need to be allocated strategically to maximize the cost effectiveness of conservation action (Kirkpatrick, 1983; Pressey *et al.*, 1993; Margules and Pressey, 2000). A key principle in systematic conservation planning is that of complementarity (Pressey *et al.*, 1993): networks of priority areas for conservation should be selected such that sites best complement each other efficiently in terms of their biodiversity composition.

The complementarity approach was explicitly proposed as an alternative to the identification of areas based on ranking (or scoring) algorithms, where the conservation value of all sites is based on a single formula, with areas sorted in descending value order and the top ones being selected (Kirkpatrick, 1983). The drawback of the ranking approach is that the top sites often capture similar mixes of species, communities or habitats, thus being highly redundant among them, and not adequately representing the overall diversity across the region. The concept of biodiversity hotspots *sensu lato* is a type of ranking system, with areas sorted in terms of their overall diversity or richness in rare species, and the top sites (hotspots) being selected. Multiple studies have found that complementarity sets are much more efficient at representing the overall diversity of a region than hotspots *sensu lato* (e.g., Kirkpatrick, 1983; Pressey and Nicholls, 1989; Williams *et al.*, 1996; not all of these studies used the term “hotspots” to designate the top areas selected through the ranking approach). The overall consensus in the conservation planning literature has thus been to discourage the use of hotspots *sensu lato* as a practical conservation planning tool. Hotspots *sensu* Myers/CI have not been designed explicitly to maximize complementarity (are not necessarily the most efficient way of maximizing overall diversity within a given area) but they are by definition complementary among themselves. Indeed, each hotspot has at least 1500 endemic plants (up to 15,000; Figure 2) and is therefore not redundant with the other regions.

Another key concept in the systematic conservation planning literature is that of irreplaceability: the extent to which the spatial options for conservation are lost if a given area is

lost (Pressey *et al.*, 1993). Irreplaceability is intrinsically connected to complementarity, because the more irreplaceable a site is the more likely that it needs to be selected as parts of a complementary set representing the overall diversity of the region. For example, if a species occurs in only one site, this is a fully irreplaceable area that will inevitably be part of all complementary networks representing all species. A complementary set often also includes low irreplaceability sites, but these are flexible, in the sense that they can be replaced by others in the region (Pressey *et al.*, 1993; Williams *et al.*, 1996). Hotspots of richness or of threat *sensu lato* are not necessarily highly irreplaceable (if the species they hold are widespread and can be conserved in other areas) but hotspots of rarity typically are. And, accordingly, hotspots *sensu* Myers/CI are regions that are highly irreplaceable at the global scale, as each one of them holds large numbers of species that cannot be found elsewhere.

Conservation implementation typically takes place over a long period of time, during which threats continue to operate and conservation opportunities may be lost. It is therefore crucial to decide not just which areas should be conserved, but which ones must be conserved first (Pressey and Taffs, 2001). Options for future conservation can be compromised in spatial as well as in temporal terms. Irreplaceability is inversely related to the degree of options in space: if a highly irreplaceable site is destroyed or damaged, it will be difficult (or impossible) to find other sites that can replace its conservation value. Site threat (or vulnerability), however, is inversely related to options in time: there is little time to conserve a site that is at high risk, opportunities must be seized soon or they will disappear. Pressey and Taffs (2001) thus proposed giving higher priority in conservation scheduling to areas of simultaneous high irreplaceability and high threat in order to minimize the extent to which conservation targets are compromised before they can be met in new conservation areas. Hotspots *sensu* Myers/CI correspond to regions of simultaneous high irreplaceability (many endemic species that cannot be protected elsewhere) and high threat (past levels of habitat loss presumed to indicate high risk into the future) (Margules and Pressey, 2000; Brooks *et al.*, 2006) and are therefore regions where conservation is urgent if global extinctions are to be avoided. It was this sense of urgency that led Myers to first propose the concept and CI to subsequently adopt it. Hotspots *sensu lato*, however, are less directly related to the extent of spatial or temporal options for conservation, particularly for diversity hotspots. Rarity hotspots correspond to areas of high irreplaceability, and threat hotspots to areas of high threat, but they do not capture the double jeopardy of simultaneously high irreplaceability and high threat.

Conservation Impact of Hotspots

Publications on hotspots *sensu lato* have been mainly academic, rather than proposing specific conservation priorities. Nonetheless, and despite the recent emphasis on complementary reserve selection, having high levels of species richness continues to be a selling point in conservation, and is a near-universal claim in the marketing materials of particular sites (e.g., “home to a stunning array of animals” in Australia’s

Great Barrier Reef; Great Barrier Reef Marine Park Authority, 2011). In some cases, species richness is still a formal criterion for site selection, for example, in identifying important plant areas (Anderson, 2002), even though the term “hotspots” is not always applied. Whereas it is conceivable that this label may increase the appeal of particular sites, it is not straightforward to quantify the extent to which the concept of hotspots *sensu lato* has had a real impact on biodiversity conservation worldwide.

Hotspots *sensu* Myers/CI, however, have from the start been proposed and advocated as very specific priority regions for conservation investment. Many of these regions are conservation priorities under multiple other global conservation schemes (such as BirdLife’s Endemic Bird Areas and WWF’s Global 200; Brooks *et al.*, 2006), and it is not easy to quantify the additional value of the “biodiversity hotspots” label for their conservation. Nonetheless, it is clear that the concept of biodiversity hotspots *sensu* Myers/CI has had a substantial impact in mobilizing globally flexible conservation investment from multilateral agencies, bilateral aid, private individuals, and corporations (Myers, 2001). In 1989, the same year Conservation International adopted hotspots as its central strategy, the Chicago-based John D. and Catherine T. MacArthur Foundation adopted hotspots as its primary global investment strategy (Mittermeier *et al.*, 2004). For the decade 2000–2010, they focused on eight hotspots (Madagascar, Melanesia, the Andes, Insular Caribbean, Albertine Rift, Eastern Himalayas, and Lower Mekong), awarding over 400 grants for US\$ 110 million (Wells *et al.*, 2010). In 2000, the World Bank and the Global Environment Facility joined CI to establish the Critical Ecosystem Partnership Fund (CEPF), a conservation finance mechanism focused explicitly on the hotspots (Dalton, 2000). They were subsequently joined by the MacArthur Foundation, the Japanese Government, and the French Development Agency. CEPF grant attribution in each hotspot is based on an “ecosystem profile”, which sets conservation targets, identifies major threats, and describes the policy, civil society and socioeconomic context, as well as funding gaps and opportunities. As of March 2011, the CEPF had committed US\$ 131 million, and leveraged a further US\$ 318 million, to over 1600 partners, spanning 53 countries and territories in 20 hotspots (Conservation International, 2011). CI’s Global Conservation Fund (GCF) also uses hotspots (along with High Biodiversity Wilderness Areas) to guide its investments. Funded by a 2001 US\$ 100 million grant from the Gordon and Betty Moore Foundation, it finances the creation, expansion, and long-term management of protected areas. As of March 2010, the GCF had committed US\$ 36 million in grants to biodiversity hotspots, to fund the creation and/or expansion of 33 protected areas, covering 7.1 million hectares (Conservation International, 2010). Overall, more than \$750 million have been devoted to biodiversity hotspots *sensu* Myers/CI, perhaps the largest financial investment in any single conservation strategy (Mittermeier *et al.*, 2004).

Criticism

Biodiversity hotspots have attracted substantial criticism, generally directed specifically at one or the other of the two main

types (e.g., Williams *et al.*, 1996; Mace *et al.*, 2000; Brummitt and Lughadha, 2003; Kareiva and Marvier, 2003; Ovadia, 2003), but sometimes in a broader and more ambiguous way (e.g., Orme *et al.*, 2005; Ceballos and Ehrlich, 2006). The main criticisms are reviewed here.

Criticism of the Hotspots *sensu* Myers/CI

Too Large

Hotspots *sensu* Myers/CI have been criticized for being much larger than the scale at which conservation decisions take place (Mace *et al.*, 2000; Brummitt and Lughadha, 2003). However, like other large-scale priority schemes, hotspots are not proposed as areas that should be entirely set aside for conservation (e.g., to be designated as protected areas), but as priority regions for concentrating geographically flexible global conservation investment (from multilateral agencies, bilateral aid, private corporations, foundations and individuals; Brooks *et al.*, 2006). Hotspots have attracted substantial funding (see Conservation Impact of Hotspots) but their ultimate conservation impact will depend on how funds are employed within each hotspot. Disbursement of conservation grants for any given hotspot under the Critical Ecosystem Partnership Fund is done after a finer scale analysis (termed an “ecosystem profile”) that identifies conservation priorities at the site scale (Key Biodiversity Areas, based on the presence of rare and/or threatened species; Eken *et al.*, 2004).

Duplication of Efforts and Lack of Consensus

Hotspots *sensu* Myers/CI and other large-scale conservation schemes have been criticized for duplicating efforts and producing competing rather than consensual proposals (Mace *et al.*, 2000). Indeed, at least nine global schemes have been proposed as global conservation priority templates, championed by different conservation organizations, following different criteria, and resulting in distinctive but partially overlapping spatial configurations (see Brooks *et al.*, 2006 for a review). Arguably their costs in terms of data acquisition, analyses, publication, and advertisement could have been pooled to produce a better and more consensual global conservation agenda, with a higher probability of adoption by decision makers (Mace *et al.*, 2000). However, different schemes may appeal to different audiences of individuals and organizations (e.g., Endemic Bird Areas to bird lovers; Stattersfield *et al.*, 1998; Frontier Forests to those concerned with carbon sequestration; Bryant *et al.*, 1997), and so multiple schemes may raise more conservation investment than a single consensual scheme would. The different priority schemes can also be seen as cooperating to attract investment to particularly important regions. Indeed, despite their apparent dissimilarity, there is substantial consensus between schemes once a distinction is made between those emphasizing regions requiring an urgent reaction to threats to biodiversity (e.g., Madagascar and Philippines) and those favoring a proactive investment in still mainly intact regions (e.g., Amazon and New Guinea; Brooks *et al.*, 2006).

Focus on a too Small Area of the Planet (Triage)

One of the strongest selling points of hotspots *sensu* Myers/CI is that they concentrate a large diversity of global plant diversity as endemics in a very small fraction of the Earth, but this has raised the criticism that the hotspot strategy advocates a sort of triage, ignoring the rest of the planet (the “coldspots”; Kareiva and Marvier, 2003), including entire ecosystems like the Arctic and the Serengeti that are not represented within hotspots. Hotspots, however, do not prescribe which areas of the planet should be written off from conservation strategies, they advocate which areas should be conserved first (i.e., which ones are priorities) for avoiding species extinctions (Mittermeier *et al.*, 2003a).

Criticism of the Hotspots *sensu lato*

Lack of Efficiency

As described above (see Hotspots and Systematic Conservation Planning), hotspots of species richness (and other ranking-based approaches for site prioritization that sort areas in descending value order, with the top ones being selected) have been criticized for being an inefficient way of representing the broader diversity of a given region, because they are often highly redundant in terms of their biological composition. Complementary-based approaches for the selection of networks of priority areas were proposed as a more efficient strategy (e.g., Kirkpatrick, 1983; Pressey and Nicholls, 1989; Williams *et al.*, 1996) and have since become firmly established in the conservation planning literature.

Sampling Bias

Patterns of species diversity are heavily influenced by sampling effort (Freitag *et al.*, 1998; Pautasso and McKinney, 2007), a pattern that may be self-reinforced as perceived high richness stimulates further attention and thus further sampling (Ahrends *et al.*, 2011). This problem affects all data-based conservation planning, and needs to be compensated by an improvement in the quality of the distribution data, or to be statistically corrected.

Broader criticism of Hotspots

The Different Types of Hotspots Do Not Match

Studies of distribution patterns of terrestrial vertebrates at the global scale found that peaks of species richness, of rarity and of threat (i.e., hotspots *sensu lato*) have reduced spatial overlap. This has been interpreted as evidence against allocating global conservation priorities based on hotspots in general (including, ambiguously, hotspots *sensu* Myers/CI; Orme *et al.*, 2005; Possingham and Wilson, 2005; Ceballos and Ehrlich, 2006) and generally bad news to conservation, because different areas are apparently needed to protect different types of species. In contrast, this lack of congruence can be interpreted as good news for conservation if conserving a maximum amount of all species diversity is the ultimate goal. Areas with high concentrations of rare species have limited spatial options for replacement, whereas areas with high levels of threat have limited options in time. Therefore, the greatest conservation challenges correspond to regions where these two

coincide – such as hotspots *sensu* Myers/CI – and it is therefore good news that a relatively small fraction of the planet suffers from this double jeopardy.

Hotspots for One Taxon are Not Necessarily Hotspots for Others

Multiple studies, at a diversity of scales, found that peaks of diversity for multiple taxa do not always overlap (Prendergast *et al.*, 1993; van Jaarsveld *et al.*, 1998; Grenyer *et al.*, 2006). As above (see The Different Types of Hotspots Do Not Match), results based on hotspots *sensu lato* have been extrapolated to criticize hotspots *sensu* Myers/CI, which have been assumed to be appropriate only for plant conservation (e.g., in Mace *et al.*, 2000, quoting results from van Jaarsveld *et al.*, 1998; Grenyer *et al.*, 2006). The lack of overlap between peaks of diversity for multiple taxa raises interesting macroecological and biogeographical questions, but it is not necessarily a conservation concern given the limited application of the concept of hotspots *sensu lato* to conservation theory and practice. In contrast, hotspots *sensu* Myers/CI have already mobilized substantial conservation investment, and if they are only effective for plant conservation that is a serious limitation to the hotspots strategy. Few studies have directly tested whether areas of simultaneously high endemism and threat for different taxa coincide, but a study investigating priority areas for expanding the global protected area network for birds, mammals, and amphibians, based on irreplaceability and threat, highlighted areas that were almost completely within the hotspots *sensu* Myers/CI (Rodrigues *et al.*, 2004).

Conclusions

More than two decades since it was first proposed, the concept of biodiversity hotspots is more popular than ever (Figure 4), but it means different things to different people. As a vague term for “important areas for biodiversity” it is no more than a sexy label, and widespread confusion about its different meanings can hinder its utility as a theoretical concept and as an applied tool. However, if rigorously defined it can have, and indeed it already has had, a significant impact in the conservation literature and practice.

This article is reproduced from the previous edition, volume 3, pp 565–580, © 2001, Elsevier Inc.

Clarification of Concepts

Island Biogeography

Biogeography is a scientific approach to understanding the distribution and abundance of living things, the biota, on our planet. Island biogeographers are primarily interested in isolated areas and the study of fragmented life zones and their relation to the biota. But what living things or biota are included? Nearly all groups are studied: plants, birds, insects, other animals, humans, fungi, fishes, disease organisms, and so on. From this list it is clear that biogeography is not a single discipline. Instead, it is a unifying principle for scientists of different disciplines. The unifying principle is their interest in the distribution and abundance of the organisms with which they have a greater familiarity. Thus, botanists, ornithologists, entomologists, mammalogists, mycologists, and anthropologists can all come together and be unified by their interest of biogeography.

Biogeographic Scales

The study of distribution and abundance of biota can be applied at any level of scale in space and time.

Spatial Scales

Traditionally, biogeographers were, and still are, interested in biotic patterns occurring at global and intercontinental scales. Geographically speaking, these are small scales that provide for broad overviews on maps or satellite images. Scientists were concerned with distinguishing and mapping large-area distribution patterns, based on landscape physiognomy, such as tropical rain forests, deserts, savannas, and temperate grasslands, commonly called “biomes.” A parallel concern was to distinguish broad patterns of species distribution, which could be mapped as “biotic provinces,” areas distinguished as different centers of biodiversity with their “own” floras and faunas. Lately, biogeographers have become concerned with distribution patterns occurring at more detailed spatial scales, such as within-archipelago migration patterns, or the distribution of biota along individual mountain slopes. Moreover, the aspect of abundance versus rareness of species and other taxa has become of concern to biogeographers, an area treated traditionally by ecologists.

Timescales

Present-day distribution and abundance patterns of biota are usually the result of past events and historical processes. Historical processes that led to present-day distribution patterns of biota are often measured at geological timescales in millions of years. Similarly long timescales are considered for biological evolution. But organic evolution by mutations and hybridization can occur at any timescale. Other timescales of biogeographic interest relate to the concepts of succession

following disturbances and to phenological change. Successional change in terms of primary succession, which refers to vegetation development on new geological surfaces, can be considered at long timescales involving hundreds and thousands of years. Primary succession can also be related to soil development (= pedogenesis). Secondary succession, defined as following disturbances on already developed soils or previously vegetated substrates, may be considered at plant-demographic timescales, involving a few years, decades, or hundreds of years, if based on the life cycles of certain long-lived tree species. Phenology relates to seasonal changes in biota. The latter two biotic change-with-time concepts—succession and phenology—were developed from ecological research in biogeography. Thus, biogeography as a research approach to discover chronological changes overlaps with those aspects of ecology that deal with distribution and abundance of biota at successional and phenological timescales and also with evolutionary research that seeks to unveil migration patterns and phylogenetic relationships over long and short timescales.

Geobotany

The term *geobotany* is derived from geographical botany, the biogeographical study of plants. In an effort to clarify Central European and Anglo-American terminology in this broad study area, Mueller-Dombois and Ellenberg (1974) synthesized the specializations within the area of geobotany in tabular form, which is reproduced in Table 1.

Biogeography was originally understood as consisting primarily of phytogeography and zoogeography. Today, following a review of recent textbooks (e.g., Cox and Moore, 1993; Hengeveld, 1990; Huggett, 1998; and others), one can consider all the ecological disciplines listed under Anglo-American equivalents (Table 1) as aspects of plant biogeography.

Three Inspiring Theories

The Theory of Island Biogeography

This theory, originally proposed by MacArthur and Wilson (1963, 1967), is practically synonymous with the concept of “island biogeography.” It proposes that species equilibria are formed on islands in relation to the size of land area and its distance from biotic source areas. An equilibrium is suggested where the rate of invasion equals the rate of extinction of island biota. These are the intersection points on Figure 1. Curves sloping from the left to the abscissa represent decreasing rates of invasion of biota, from near to far source areas; curves sloping from the zero point on the abscissa up to the right ordinate represent increasing rates of extinction, from large to small islands. The curves are based on a complicated

mathematical model. However, the model is easily understood from Figure 1. For example, a large archipelago, such as the Fijian Islands, situated nearer to continental source areas for the dispersion of biota, would have richer species equilibria than a large archipelago, such as the Hawaiian Islands, which is much farther removed from any biotic source area.

The reality of species equilibria is highly questionable, yet the theory has been and continues to be very inspirational. If applied not simply to species per se, but instead to different life forms, such as indigenous trees, ferns, or shrubs, the results may show differing values of species richness and endemism in relation to size of island areas and degrees of

Figure 1 The MacArthur and Wilson (1963, 1967) models of dynamic species equilibria as controlled by distance of islands from biotic source areas (from near to far) and by size of islands (from small to large). Reproduced from MacArthur RH and Wilson EO (1963) An equilibrium theory of insular zoogeography. *Evolution* 17: 373–387 and MacArthur RH and Wilson EO (1967) *The Theory of Island Biogeography*. Princeton, N.J.: Princeton University Press.

isolation. Moreover, these in turn may lead, with additional ecological studies, to a better understanding of the function of biodiversity in different island ecosystems.

At this point, another limitation of this theory should be mentioned. This relates to the fact that size of island area is only a most general predictor of species richness. At least elevational range and substrate type should be added to make the theory more predictable. This brings us to the next theory.

The Biome Theory

This theory predicts that there are broad life zones that are indicated by groups of biota of key plant life forms, which are controlled by certain broad-area climatic and edaphic (soil) parameters. For example, the biome theory predicts that in mountainous environments there are altitudinal life zones (Holdridge, 1967) or vegetation zones (Mueller-Dombois and Ellenberg, 1974) that can be distinguished by tree species and other life forms into lowland, upland, and high-altitude zones. Also, such familiar terms as *desert*, *grassland*, *deciduous forest*, *coniferous forest*, and *tundra* depict different latitudinal biome types, which in turn can be defined by climatic parameters as “zonobiomes” (Walter *et al.*, 1975). It is assumed that conditions for life within a biome are more homogenous than life conditions across different biomes (such as grassland versus desert).

Applied to island biogeography, the biome theory lends itself to a more appropriate refinement in the analysis of biodiversity than is offered by the two ecosystem parameters—size and isolation—in the above described theory of island biogeography. For example, comparative biodiversity research within a Pacific-wide biome type, such as the montane rain forest on volcanic high islands of basaltic origin, is scientifically more satisfying than biodiversity research based simply on size of island area. The size approach groups different types of islands into the same category, which thus can be a very

Table 1 Areas of specialization within the field of Geobotany, their synonyms, and Anglo-American equivalents

Area of specialization (and synonyms, European terms)	Subject matter	Anglo-American equivalents (and synonyms)
Floristic geobotany	Study of geographic distribution of plant taxa and their evolutionary relationships	Plant geography (phytogeography)

Figure 2 Latitudinal gradients of mean annual rainfall in eastern Micronesia, from the northern Marshalls to the southern Gilberts (Kiribati) and Ellice Islands (Tuvalu), summarized by Fosberg zones. Adapted with modifications from Stoddart DR (1992) *Biogeography of the tropical Pacific*. *Pac. Sci.* 46: 276–293.

heterogeneous category that includes atolls, raised limestone, and volcanic high islands. Using the biome theory, environmental gradients can be studied among physically similar islands. Examples of environmental gradients for island research

of the same biome type are given in [Figure 2](#). Atoll and reef islands can be considered as belonging to the same biome, in this case, the same “pedobiome,” meaning they have similar, marine-derived, substrates and similar low elevations.

The Theory of Succession

Both the island biogeography and biome theories thus outlined contain elements of succession or community and ecosystem development. MacArthur and Wilson (1967) speak of five fundamental processes as the most difficult to study in biogeography. These are listed as (a) dispersal, (b) invasion, (c) competition, (d) adaptation, and (e) extinction of species. In his concept of succession, the early, influential American ecologist Clements (1916) recognized six processes: (a) nudation, (b) migration, (c) ecesis (establishment by reproduction), (d) competition, (e) reaction (habitat change through organisms), and (f) final stabilization, the climax community. All of these processes are of concern in biogeographic research. For example, the process of "dispersal" and "migration" of species among islands and their "adaptation" in terms of speciation were chosen as the main topics in a recent treatment of Hawaiian biogeography (Wagner and Funk, 1995). Other processes, such as the establishment and regeneration of populations (ecesis) after major disturbances (nudations), their "invasion" relative to "extinction" or their "final" assemblages in communities or ecosystems, also fall into the realm of biogeographical research. Clements proposed a final stabilization, called climax, while MacArthur and Wilson proposed a dynamic (final) species equilibrium as explained earlier. Both, the climax and species equilibrium concepts have been severely criticized. Yet dynamic equilibria remain an area of ecological and biogeographical interest because an understanding of dynamic processes is essential for an improved theory of island biogeography.

In connection with our long-term research on the native *Metrosideros* forest dieback in Hawaii, I introduced a model

of ecosystem development based on the theory of succession (Mueller-Dombois, 1986). This is diagrammatically portrayed in Figure 3. The model addresses the concepts of climax as well as those of primary and secondary succession and habitat change with time in a single island biome, the montane tropical rain forest of Hawaii. Here, the process of nudation can be a new pāhoehoe lava flow or a volcanic ash blanket. Both, the volcanic ash and pāhoehoe substrates, may achieve a "climax" in vegetation development in about 1000 to 5000 years in the rain forest climate. After that, a regression phase sets in very slowly, characterized by cation leaching, increasing occlusion of phosphorus (Crews *et al.*, 1995), formation of secondary aluminum (gibbsite) and iron (goethite) minerals, and advanced desilication (Fox *et al.*, 1991). With time, here estimated as 1 million years, the forest undergoes a number of generation turnovers in the form of canopy breakdown or gap formation and recovery. These may be synchronized over larger or smaller areas, depending on the disturbance regime, the cohort structure, and the aging pattern in the forest mosaic. The different kinds of dieback or canopy failure, depicted on the diagram as demographic events, reflect the habitat changes in terms of soil water and nutrient relations that occur over the long timescale. The model also implies that after the plant biomass or biophilic nutrient climax, forest recovery yields successively less tall *Metrosideros* forests. Associated with the progressive and regressive phases of ecosystem development, different species assemblages also occur. Species equilibria have not been detected among native species. The question of invasive nonnative species is a separate major problem of island biogeography that is discussed in another chapter of this book.

Figure 3 A model of primary succession and regression in the Hawaiian rain forest biome with superimposed secondary successions as caused by *Metrosideros* canopy failures. These are related to demographic growth cycles and the climatic disturbance regime. A "climax" is shown by the maximum in plant biomass and biophilic nutrient availability. After this climax, indicated mainly by the height of *Metrosideros* canopy trees, the regression phase is caused by leaching of cations, occlusion of phosphorus, and complete desilication. Reproduced from Mueller-Dombois D (1986) Perspectives for an etiology of stand-level dieback. *Ann. Rev. Ecol. Syst.* 17: 221–243.

Vegetation Analysis Methods

Floristic Checklist Methods

"Floras" are lists of plant species. When more elaborate, they are books with species descriptions, keys, and illustrations for plant identification. Floras usually give little information on vegetation, which is the most visible component in terrestrial ecosystems, there performing the function of primary producer. "Vegetation" is the plant cover of an area in which species play different roles in terms of their abundance or rareness and in terms of their life forms, life histories, and physiology. In nature, plants often interact with one another in communities. "Plant communities" can be distinguished by differences in life-form structure—such as forests versus shrub- or grassland—or by differences in species assemblages. In the study of island biogeography, floristic checklist methods can be applied at the level of biogeographic provinces, which may serve for floristic comparisons of archipelagoes. They can also be applied among individual islands of the same archipelago. At both these broad levels of scale, tests of similarity versus dissimilarity can be applied from floristic records or subregional floras where these exist. However, field research is needed if one wants to compare the floras within the same biome on different archipelagoes, because this information is usually not available. A simple "walk-through method" can provide this information without formalized sampling designs, such as plots or transects. Such broad floristic surveys also help in familiarizing with the territory and, when used together with aerial photographs and topographic maps, they can result in vegetation maps outlining tentative communities. However, floristic comparisons among communities of the same biome in an archipelago, such as the rain forest across the high Hawaiian islands, require a more formalized checklist method in representative sample plots, such as described by the relevé method (Mueller-Dombois and Ellenberg, 1974, discussed later).

Vegetation Sampling Methods

A number of field methods are available. Their proper use depends on the purpose of sampling and the type of vegetation. Here, I will consider plant biodiversity as the general objective of sampling.

The Relevé Method

This is a widely applied and proven floristic checklist method, ideal for many, if not most, plant biodiversity surveys. It is based on plots, called relevés (meaning abstracts), whose sizes are based on the "minimal area concept."

Determining Relevé Size

A minimal area for vegetation sampling can be established by the "nested plot technique." This technique consists of lining out a small quadrat, 0.5×0.5 m, and then enumerating all species encountered in this small quadrat. Next, the quadrat size is doubled into a rectangle of 0.5×1 m, and additional species are noted. The next doubling is a 1×1 m quadrat, followed by 2 m^2 , then $4, 8, 16, 32, 64 \text{ m}^2$, and so on. At each enlargement, the new species encountered are added. When

plotting the cumulative number of species over the area sample, a species/area curve is obtained. In a homogenous vegetation segment, this usually takes the form of a steeply rising curve that levels off with each enlarged quadrat. The result is a curve of "diminishing returns" in terms of number of species encountered with still greater enlargement of area. The area over which the curve levels can be used as the "minimal area." The usual practice is to use a slightly larger area for the size of a relevé. In temperate grasslands, a 10×10 m quadrat is often sufficient to satisfy the minimal area requirement. In temperate forests, 20×20 m quadrats may give a satisfactory relevé size. In multispecies tropical rain forests, 1 ha ($10,000 \text{ m}^2$) may not be large enough (see Figure 4). But 1 ha is now often considered a practical standard for biodiversity research of tropical rain forests.

Recording Species in Layers

A relevé record should contain all plant species found in its boundaries. In forest communities, recording is best done in horizontal layers by vertically defined height strata. For example, one may distinguish two tree layers T1 as trees over 10 m tall, T2 as trees from 5 to 10 m tall (subcanopy trees), then a shrub layer from 2 to 5 m (including smaller trees), then a lower shrub layer from 1 to 2 m high, and further a herb layer from 0 to 1 m high, including smaller woody shrubs and trees (usually seedlings). The vertical stratification is an aid in recording. It also can document if canopy trees are regenerating in the same sample stand (or relevé).

Distributing Relevés in Predefined Strata

Relevés are best laid out in predefined strata. On mountain slopes, these may be predefined elevational strata, such as 200 m contour intervals or the like. In other areas, these are the tentative vegetation segments or communities identified on air photos in conjunction with field reconnaissance and check listing. We have called this process "entitation" (Mueller-Dombois and Ellenberg, 1974), which means defining of entities or map units from air photographs. Depending on the scale and homogeneity of the initial strata or entities, from 2 to 5 relevés are often used to characterize a stratum or entity. Also, depending on the size and complexity of plant biodiversity in an area, from 20 to 140 relevés can amount to a satisfactory biodiversity survey in terms of plant species and plant communities.

Estimating Species Quantities

The relevé method as described here is merely a formalized floristic checklist method, which reports the presence (and absence) of species. For classifying plant communities it is desirable to record how abundant or rare a species is in an area. This can be done simply by adding an abundance symbol to each species on the relevé record sheet. The most widely used rating system in European vegetation surveys is the Braun-Blanquet cover/abundance scale consisting of seven symbols as follows:

- 5 Any number of individuals, with cover more than 3/4 of the reference area (>75%)
- 4 Any number, with 1/2 to 3/4 cover (50–75%)

Figure 4 Species/area curves for sites with tropical rain forests in Brunei. Redrafted with modifications from Ashton PS (1964) Ecological studies in mixed dipterocarp forests of Brunei State Oxford Forestry Memoirs, no. 25.

- 3 Any number, with 1/4 to 1/2 cover (25–50%)
- 2 Any number, with 1/20 to 1/4 cover (5–25%)
- 1 Numerous, but less than 1/20 cover, or scattered, with cover up to 1/20 (5%)
- + Pronounced cross) few, with small cover
- r Solitary, with small cover

This estimation scale is applied by walking diagonally through the relevé, several times if necessary. It is a crude scale and thus is often criticized, but it takes little time and tells a lot more about the plant composition of a relevé than a mere presence/absence record.

However, estimation methods are often not satisfactory in more complex vegetation. In forest vegetation it may be usefully applied only to the undergrowth species and only in relevés that are small enough to allow such estimation with confidence.

Quantitative Methods

In forest vegetation it is not possible to get a satisfactory estimate of the quantity of tree species by the cover/abundance scaling method as described earlier. In such more complex vegetation, at least the tree component needs to be measured to obtain a satisfactory abundance or cover estimate. The reason for this is primarily that relevé sizes are too small for obtaining an adequate density or cover estimate of trees.

The Count-Plot Method

To get an adequate estimate of tree density per unit area, such as a hectare, one should count trees in many small plots, such as 3×5 m. The small size of such count plots is merely a convenience for an accurate (100%) enumeration per plot. Larger

plots may lead to accidental double counts or omissions, thereby introducing serious errors. Count plots are conveniently laid out along transects. They must be repeated until the cumulative mean number of trees does not fluctuate anymore radically with each additional count plot. This may be accomplished by counting at least 30 to 50 trees/species. It is obvious that rare tree species can hardly be adequately counted by this method. Rare tree species can only be reasonably assessed by searching an area of known size for such species, thereby attempting a 100% survey of their presence. In counting trees as a measure of tree density per unit area, it is necessary for plant biodiversity surveys to count trees by species and by measuring some tree-size parameters. Among tree-size parameters, usually the diameter at breast height (Dbh) is measured. From this, tree basal area is obtained by the area formula $r^2\pi$. However, the true basal area is the stem cover at ground level. Where this parameter is desired, one needs to measure also tree diameters at ground level. The Dbh measure is usually preferred in timber volume surveys. Tree volume is established by combining the basal area with a height measure and a tree form factor. More elaborate formulas can be developed for total tree biomass, often sought in productivity studies.

Distance Methods

An alternative to the count-plot method are the distance methods. They often lead more rapidly to an adequate count of trees, since they do not require the layout of plot boundaries. Instead, the average distance between trees is used to determine the mean area per tree and thereby the density per

unit area. The mean area per tree is obtained by squaring the mean distance. This method works well under certain restrictions. Two methods are briefly outlined.

The Point-Centered Quarter Method

A random starting point is established in the forest to be measured. Four distances are measured from this point to the nearest tree in four quarters, forming each a 90° exclusion angle over the point. The sampling point therefore is used like a rectangular cross, and the distance from the point to the nearest tree is measured in each quarter. When repeated at 20 sampling points, established at random or along a compass line, one obtains 80 distances. The mean distance squared then gives an estimate of the mean area per tree. The number of trees per acre (= 4000 m²) or hectare (10,000 m²) is obtained by dividing such reference area by the mean area/tree. The point-centered quarter method is relatively simple to apply, and it compares well to the count-plot method. However, two restrictions apply: the trees should be randomly distributed, and no tree should be measured twice. The second requirement is usually easy to follow as it requires that the sampling points are far enough apart so that no tree is measured twice.

The Wandering Quarter Method

This second recommended distance method is often less affected by the distribution pattern of trees (random versus clumped) as it traverses for the same number of distance measures through a larger area. The method begins with establishing a random sampling point in the forest segment to be sampled. A 90° exclusion angle is established in a certain compass direction, and the nearest tree to the sampling point is measured. That nearest tree then becomes the next sampling point over which a 90° exclusion angle is established in the same compass direction. From this tree the distance is measured to the next tree in that exclusion angle. The procedure is continued for 20 distances in that same direction, moving from tree to tree and always using the same 90° exclusion angle. This results in a wandering movement or zigzag line depending on where the next tree occurs within the 90° exclusion angle. After 20 distances, the direction may be changed following a right angle for another 20 distances, then once more at a right angle in a parallel reverse direction to the first zigzag line, and finally, 20 distances in direction of the starting point. In this case, the sampling also includes 80 distances, but the area traversed is larger than in the point-centered quarter method.

Measures Obtained in Count-Plot and Distance Methods

The two types of methods provide for the same three parameters desired often in quantitative vegetation surveys. These are frequency, density, and cover.

"Frequency" is simply the occurrence of a species in any number of plots in relation to the total number of plots in the sample. In the distance methods, frequency is the occurrence of a species at a sample point out of the total number of sample points. Frequency is a mixed measure of abundance and dispersion or distribution. It is a relative measure as it depends on the plot size used in sampling.

"Density" is the actual count of individuals per species in the total number of count plots. The sample plot area is then

adjusted to a standard reference area, such as a hectare. In the distance methods, the number of individuals is obtained from squaring the mean distance of all trees and dividing this measure into the reference area. The number of individuals per species is then obtained from the proportion of species among the total number of individuals.

"Cover" as stem cover per species is obtained from totaling the individual basal area measurements in the sample of count plots or points and by relating this measure to the reference area. For examples, see Mueller-Dombois and Ellenberg (1974).

Another aspect relates to the tree-size stratification in count-plot and distance sampling. In addition to sampling mature trees/species, it is ecologically desirable in biodiversity inventories to also establish the density of seedlings and saplings. First, mature trees have to be defined. This is often done by setting height and/or diameter limits. "Mature trees," for example, may be all individuals 5 m and taller, thereby forming a broad size class. "Saplings" may be defined as individuals from 0.5 to 5 m tall and "seedlings" as those from 0.1 to 0.5 m tall. Smaller individuals may be considered as "germinants" (i.e. not yet well established or ephemeral individuals). Smaller subplots are often required for seedling counts because of their smaller size and frequently greater density. In the distance methods, usually only mature trees are measured because of the random pattern requirement for accuracy. In such cases, seedlings and saplings may be counted in subplots of appropriate sizes at predetermined sampling points.

Application of appropriate sampling methods requires some basic understanding of sample theory and field experience. When the sampling objective is clarified and the nature of the vegetation experienced, it is usually possible to prescribe an appropriate approach from a combination of established field analysis methods.

Size of Sample Plots

Figure 5 displays six sample plot sizes that have been used in proven studies. They are drawn to the same scale. Like the small, 20 × 10 m grassland relevé, all plots were placed in predetermined entities or tentative map units to obtain representative data. Daubenmire's (1968) preferred plot size of 15 × 25 m was applied in the mountainous interior forests of the Pacific Northwest. He preferred to assess the undergrowth vegetation within such plots along 25 m transects by determining frequency out of 50 systematically placed 0.1 m² frames. Percent cover in terms of shoot cover was also estimated similarly as with the Braun-Blanquet cover/abundance scale. But 50 placements only gave an area sample of 5 m², which likely did not fulfill the minimal area requirement as used in the relevé method. The larger plots in Figure 5 refer to quantitative studies as discussed earlier. Their sizes are based on the principle that tree species need to be counted in numbers that give reliable density and basal area estimates.

For obtaining a minimum tree count of 30 to 50 trees/species, larger plot areas are needed, since individual mature trees can occupy mean areas of 25 to 100 m² or larger.

The larger sample plots with quantification of tree counts obviously require a much greater time effort than a relevé with a species record supplied with a cover/abundance estimate. Thus, one has to be very clear about the purpose of the field effort. The relevé method is particularly useful in plant biodiversity studies aiming at classifying vegetation by species groups, while quantitative methods are essential if the objective is repeated monitoring of plant biodiversity in permanent plots.

Data Processing and Display Methods

Data Analysis: An Island Example

During the 1970s, we did a multidisciplinary study in Hawaii under the auspices of the International Biological Program (IBP). Our main objective was to study the biological organization in relatively undisturbed natural communities. We focused on two areas, an upper montane rain forest (the Kilauea Rain Forest) and the east-slope of Mauna Loa in Hawaii Volcanoes National Park (Figure 6). In the Kilauea Rain Forest, which was dominated by three native keystone

Stroudsburg, PA: Hutchinson-Ross.

besides plants. For the plant distribution study, we established 48 relevés throughout this mountain transect, approximately three relevé clustered around each of the 14 transect sites.

Two-Way Table and Dendograph Techniques

Following the field study, the 48 relevés were processed by the "two-way table technique." That required entering all relevés into a single "raw table," whereby the relevé number appears at the head of the table and all species names appear at the left side of the table. The species magnitude, or score values, are entered for each species in the respective "relevé columns." When all data are entered in this way, one can see in the "species rows" which species are present (and with what score value) or absent in the "relevé columns." The process then begins of sorting species of similar distribution together by repositioning the "species rows," then also the "relevé columns" are resorted to bring those relevés together in the table that contain species of similar distribution. The "row and column sorting process" is reiterated until the table displays an optimal structure in the sense that one can interpret the clustering of species and relevé group in an ecologically meaningful way. This data processing, formerly done by hand, can now be done mathematically by using one of many multivariate analysis techniques and similarity indices.

An example of a two-way table extract of our 48 Mauna Loa relevés is given in Table 2. For corroboration of species distribution and relevé clustering trends one can use various mathematical ordination methods or data classification methods. Ordination methods (not illustrated here) present the same data geometrically, while classification methods present the same data in the form of dendrographs (see Figure 7). The three data processing and display techniques are corroborative analytical tools. Particularly the ordination and dendrograph techniques are rather abstract and difficult to interpret by the reader.

Improved Display Methods

It is more "reader friendly" to go a step further in displaying the results of a multivariate data analysis as shown in Figure 8. This data display over the Mauna Loa transect with its 14 IBP transect sites clarifies that both multivariate analyses, the two-way table and the dendrograph techniques, gave closely similar results. Both data treatments resulted in the definition of seven altitudinal vegetation zones as named in the legend of Figure 8.

The answer to MacArthur's (1972) question is given in Figure 9. It displays the distribution of 17 key species, which are primarily responsible for the pattern of the seven vegetation zones identified by multivariate techniques. Several species clearly change synchronously, while others have independent distributions along this island mountain slope. The answer to MacArthur's question is this: There is more than one pattern of plant species distribution along this geologically young tropical mountain slope. Some distributions coincide closely with one another; others do not. However, the species distribution data give clear evidence of the existence of altitudinal vegetation zones as established from mathematically independent multivariate analysis techniques.

An Experimental Sampling Design For Island Biogeography Research

Transects are generally the most efficient sampling designs in ecological field research. They can often be arranged to cut through a maximum of variation in representative habitats and biodiversity assemblages of an area to be studied, using the shortest distance. A still more important aspect is the use of transects to control environmental variation in its effect on biodiversity. In this way, transects can be used as "experimental sampling designs" by aligning them along changing environmental control factors to study their effects on biodiversity in environmental settings that are relatively uniform or constant. Sampling transects along a mountain slope, on which mean annual temperatures and rainfall change in predictable ways, are good examples. Another example is given

in Figure 2, in which the western Pacific atoll islands are aligned along mean annual rainfall gradients in both the northern and southern hemispheres.

Horizontal within Ecosystem Gradients

In addition to the atoll islands there are several other Pacific-wide biomes. A particularly important one is the upland rain forest on the volcanic islands of the tropical Pacific. This forest is important for two primary reasons: it is still extant on many volcanic high islands as indigenous forest harboring most of the endemic species, and it performs the function as watershed cover in the mountainous interiors of these islands. The volcanic high islands typically are small, isolated land fragments that protrude as mountainous terrain above the vast Pacific ocean surface. Their interior upland forests likewise are fragments that belong to the same larger ecosystem or biome. However, from archipelago to archipelago, these biome fragments are occupied by different sets of species due to their past biogeographic isolation. Connecting these biome fragments horizontally across the ocean by a system of transects provides for a within-biome research design. Here, the broad habitat features are kept uniform, while the indigenous biodiversity sets change from island to island. This truly is a research approach to biodiversity, which Pielou (1979) defined as "geocology," the study of recurrence of similar communities in similar habitats, which are occupied by different sets of species. The term *geocology* is an abbreviation of geographical ecology in the conceptual sense used by MacArthur (1972), who contributed substantially to the foundation of island biogeography.

Vertical Between Ecosystem Gradients

A functioning watershed cover is an essential resource component in all Pacific high islands. From here, the fresh water flow begins to be regulated and then influences almost all lower lying island ecosystems, the freshwater wetlands, mangroves, estuaries, fish ponds, fringing reefs, the entire coastal zone, and agriculturally used lowland areas. The ecosystem services of the upland forest watersheds have not been studied in the Pacific islands, in spite of the fact that they have been part of the traditional land-use system in the Pacific high islands, in Hawaii known as the ahupua'a system. This vertically arranged land-use system was recognized in the Hawaiian Islands as comprising four integrated management zones, "wao la'au," upland forest or wilderness area, to be left alone, "kula," the more open foot hill region, "wao kanaka," the agricultural zone in the lowlands, and "kahakai," the coastal zone. This vertically arranged multi-ecosystem human support system proved to be an optimal land-management scheme for the indigenous islanders in the past. Vertically arranged transect sites, using the fresh water flow and hydrology as unifying parameter, may also prove to be a good organizing principle for interdisciplinary research focused on the function of biodiversity at the landscape level.

The PABITRA Initiative

The acronym PABITRA refers to the Pacific-Asia Biodiversity Transect outlined on Figure 10. The transect system connects the high island archipelagoes with indigenous tropical rain forests still extant in their interior uplands. They range

Figure 10 The PABITRA (Pacific-Asia Biodiversity Transect) network as currently being initiated. For more information see text.

from east to west, from the paleotropical outlier islands, the Hawaiian archipelago and the Marquesas, to the biotically rich continental islands of southeast Asia. The PABITRA concept arose from the concluding chapter of a recent book (Mueller-Dombois and Fosberg, 1998) with the chapter heading "The Future of Island Vegetation." Simply put, the indigenous island vegetation only has a future if the scientific community and conservation managers redouble their efforts in learning to understand the function of island biodiversity and thereby take appropriate conservation measures. Another impetus came from a Japanese research initiative, called DIWPA, Diversitas in the Western Pacific and Asia. This program is the Pacific-Asia representative of the new worldwide program "DIVERSITAS," promoted by the International Union of Biological Sciences (IUBS) with support from UNESCO and ICSU (The International Council of Scientific Unions in Paris, France). The promotion of DIVERSITAS started effectively with a week-long forum titled "Biodiversity, Science and Development: Towards a New Partnership" in September 1994 (Younès, 1996). Since then, DIWPA has focused on a "Green Belt," a north-south transect in western Asia for monitoring biodiversity of forests and freshwater lake systems at 42 transect sites. A parallel running "Blue Belt" is also planned with focus on coastal zones and nearshore marine habitats. The PABITRA Initiative is considered a separate, but attached, "Pacific Island Branch of DIWPA," working cooperatively under the Ecology, Conservation, and Environmental Protection (ECEP) Division of the Task Force on Biodiversity in the Pacific Science Association, which is chaired by the writer.

Landscape Ecology and Population Dynamics

Scott M Pearson, Mars Hill College, Mars Hill, NC, USA

Published by Elsevier Inc.

Glossary

Core and satellite model Network of habitat patches in which centrally located core patches harbor stable populations that provide emigrants (or colonists) to ephemeral populations in peripheral satellite patches.

Deme Localized breeding group or subpopulation, often confined to a single habitat patch.

Effective population size (N_e) Number of individuals in population that participate in breeding.

Extinction vortex Complex of interacting mechanisms that lead to the extinction of small populations.

These mechanisms include loss of genetic diversity as well as environmental and demographic stochasticity.

Habitat fragmentation Process in which habitat loss converts a landscape dominated by large connected patches

of habitat to one in which habitat exists in small, disconnected patches or a condition in which habitat is spatially distributed as small, disconnected patches.

Landscape matrix The complex of habitats occupying the space between habitat patches.

Metapopulation Network of individual demes connected by the processes of immigration and emigration.

Population dynamics Change in population size through time and the processes that bring about these changes.

Sink population Deme in which death rates exceed birthrates. Sink populations will go extinct without an input of immigrants.

Source population Deme in which birthrates exceed death rates. Sources produce an excess of individuals that emigrate from that deme.

Introduction

The discipline of landscape ecology emphasizes the causes and consequences of spatial pattern on the functioning of populations, communities, and ecosystems. Nature is generally not homogenous with respect to ecological properties. Those properties include gradients in abiotic factors, such as the temperature, moisture, and the abundance of required resources; and biotic factors, such as the presence of predators, pathogens, and competing species. This spatial heterogeneity exists at multiple scales of space and time. The term “landscape” evokes patterns over a broad scale, such as the view from an airplane or satellite extending over several square kilometers and including the mosaic of forests, grasslands, wetlands, agricultural fields, and urban areas seen below (Figure 1). This mosaic and the diversity of habitats therein is the setting where species make their living. The spatial pattern of habitats determines how species and their populations are distributed across this view from above. The influence of spatial pattern is also important at finer scales. Studies in landscape ecology have illustrated how the spatial pattern of resources at the scale of 1 m² altered the habitat use by beetles and ants (Wiens and Milne, 1989; Wiens *et al.*, 1993). “Scale” is an important concept in landscape ecology because the influence of spatial patterns often depends on the scale in which they are observed and measured. It is common to measure spatial heterogeneity at multiple scales in order to best discern which scales are important for a given ecological phenomenon (e.g., Price *et al.*, 2005). No matter what scale is studied, the spatial pattern of resources alternatively provides opportunities for population spread and increase, limits and constrains population growth, or threatens the persistence of some species.

Basic Concepts and Terminology about Population Dynamics

A population is a group of interbreeding organisms that produce viable, fertile offspring; under the biological species concept, members of a population belong to a single species. Localized breeding groups are also known as “demes.” In a typical landscape, the suitable habitat for most species exists in a patchy pattern (Figure 1), so patches of habitat usually define the location and boundaries of demes.

Ecologists are interested in the number of individuals in a population (that is, population size classically denoted by the letter N). The change in N through time (dN/dt) is population dynamics. Population size changes by the demographic processes of birth, immigration, death, and emigration (BIDE). This BIDE model of population growth is

$$dN/dt = \text{Births} + \text{Immigrants} - \text{Deaths} - \text{Emigrants}.$$

Populations in which immigration and/or emigration occurs are considered to be open populations and are connected to other demes by the movement of individuals. The distances between demes influence the frequency of these deme-to-deme movements. Movements may happen regularly for the population but occur infrequently during the life cycle of an individual. Movements often take the form of dispersal from the natal site to a different habitat patch. Dispersal lessens the probability of competition and interbreeding with parents and siblings, especially when the population in the natal patch is small. Analyses of population viability and genetic diversity emphasize effective population size (N_e), which is the number of individuals actually participating in breeding. In most populations, $N_e < N$ because some individuals are unsuccessful in attracting a mate, reproductively immature, or of postreproductive age.

Population Dynamics in Landscapes

The number of individuals in a population, N , is limited by available resources. The limiting resource(s) may include food or nest sites for animals, or moisture, sunlight, and/or soil nutrients for plants. Suitable habitats are the locations and conditions that provide these resources. Given that resources are finite, N has a maximum value that is sustainable. Ecologists use the term carrying capacity (K) to refer to the maximum N that a given environment can support over the long term. The logistic growth equation is a simple model of population dynamics learned by most students of ecology:

$$\frac{dN}{dt} = rN \left[\frac{K - N}{K} \right]$$

The value dN/dt represents change in N over a unit of time (t), and r is the intrinsic rate of increase, which is a measure of per capita population growth:

$$r = \frac{\text{births} - \text{deaths}}{N}$$

Assumptions of this model include a closed population (i.e., there is no immigration or emigration) and that r and K are constants. Other ecological forces that could influence population growth, such as predation or competition, are not included. The logistic growth model implies that a population attains equilibrium with resources in its environment. The continuous form of this model produces graphs of N against time as an S-shaped curve in which the population grows until $N=K$ and then N remains constant at that value. The assumptions of the logistic growth model are rather restrictive, and very few if any populations in nature would fulfill all of them. Nevertheless, it expresses a central premise that populations are limited by availability of resources and the amount of habitat in the landscapes where they live. Furthermore, landscape ecologists study how the spatial arrangement of habitat patches can alter population dynamics.

Landscape-level changes in habitat abundance and spatial pattern affect population dynamics. Data on populations of grassland birds in North America provide example of how changes in habitat availability alter population size. At the continental scale, the abundance of bird species that require grassland habitats has been declining since the mid-1900s in

Figure 2 Change in abundance for grassland birds at (a) continental scale for eastern North America and (b) regional scale for Illinois. North America (Peterjohn and Sauer, 1999; Figure 2) and parts of Europe (Chamberlain and Fuller, 2001; Figure 2). These declines can be explained by the loss of grassland habitats because of changing agricultural practices, expansion of suburban development, conversion of grassland habitats to forests, and long-term disruption of ecological processes (e.g., fire and grazing) that create and maintain grassland habitats (Askins *et al.*, 2007). Landscape-level analyses have revealed the specific habitat features required for foraging and nesting by these birds (Ribic and Sample, 2001; Veech, 2006). These species are sensitive to the fragmentation of their habitats. In response to these population declines, management initiatives at the regional scale have focused on habitats protection and restoration. One such initiative is the US Department of Agriculture's Conservation Reserve Program (CRP). The CRP encourages the protection of large patches of grassland habitat and has the potential to increase habitat availability for these birds. Herkert (2007) documented an increase in Henslow's sparrow (*Ammodramus henslowii*), an obligate grassland species, in response to the establishment of 400,000 ha of CRP lands in Illinois (Figure 2) but cautioned that local management practices (such as farmers' mowing schedules) can affect habitat quality. The positive effects of similar habitat restoration efforts have been documented in other regions (e.g., Benson *et al.*, 2006).

Monitoring population dynamics at the landscape scale is challenging. Various survey techniques are available for estimating population size, but measurement of demographic rates is more difficult. It is generally necessary to estimate demographic rates (i.e., births, deaths, and immigration) by sampling a limited number of sites or habitat patches in the landscape because of the large effort required to produce these estimates. Often it is the variation in demographic rates among habitat patches that is of greatest interest. For example, Herkert *et al.* (2003) sampled 39 sites to estimate the effects of patch size on nest survival and parasitism in three grassland bird species. In a study of song sparrow (*Melospiza melodia*)

populations, Jewell and Arcese (2008) linked the population growth rates of the sparrows indirectly to landscape-level patterns of land use (Figure 3). Rates of brood parasitism by cowbirds (*Molothrus ater*) reduced sparrow reproduction, and cowbird abundance was strongly correlated with land uses such as urban and agricultural lands with livestock grazing. These land uses created areas where parasitism rates were so high that local reproduction in sparrow populations could not replace individuals lost to mortality (i.e., $r < 0$). Their results suggest that these populations were maintained by immigration from areas with lower parasitism rates rather than by local reproduction.

Simulation models are often employed to explore the effects of landscape patterns on population dynamics. Spatially explicit models can simulate the occupancy of specific locations as well as the demographic rates characteristic of populations at those locations. Such models allow the researcher to test hypotheses about population dynamics in the complex settings of real and theoretical landscapes. These models are especially useful for studying the impacts of various scenarios of landscape change on populations. Pearson *et al.* (1999) examined how management options related to forest clearing would affect habitats, and therefore the abundances, of a suite of native species. Complex population processes such as survival, reproduction, and movement of individuals can be represented in spatially explicit models. For example, Holdo *et al.* (2011) used a model to study the impact of road construction that would interfere with migratory movements of the Serengeti wildebeest (*Connochaetes* spp.; Figure 4). Their simulations suggest that this barrier to movement could reduce wildebeest population by one-third because these animals would be less able to migrate to the most productive foraging sites. Locations of the most productive sites shift in location seasonally, and the road interfered with the animals' ability to track and migrate to those sites. Moreover, the road was predicted to divide a single wildebeest population into two separate subpopulations.

Figure 3 Maps of brood parasitism and population growth of song sparrows (*Melospiza melodia*) in the Southern Gulf Islands of British Columbia, Canada. Rates of parasitism by brown-headed cowbirds (*Molothrus ater*) (a) are affected by land use and results in variation in population growth rates of their sparrow hosts (b). Growth rates are expressed in terms of finite rates of increase. Rates ≥ 1 indicate stable or growing populations (sources), whereas rates < 1 represent declining or sink populations. Although the overall abundance of required resources is of great importance for populations, the patchiness and spatial arrangement of habitat types have the potential to complicate population dynamics in landscapes. Demographic rates, such as survival and reproduction, may be affected by

patch size and shape. Movements between patches can be influenced by the distance between patches and other spatial features. Therefore, an understanding of how population dynamics play out in space is important for research and management.

Landscape Structure and Population Dynamics

Landscape ecologists are interested in spatial patterns. For populations, the overall abundance of habitat and its spatial distribution have a strong influence on the genetic structure and population dynamics of species. The concepts of patch, matrix, and corridor are useful for understanding how populations are influenced by the spatial structure of landscapes (Figure 5). For the time being, assume that patches are recognizable as discrete areas of similar habitat and that all habitat patches contain suitable habitat with enough resources to sustain a population. (This assumption of discrete, homogeneous patches will be relaxed later.) The unsuitable habitats found between habitat patches comprise the landscape matrix. Corridors are linear strips of habitat that connect patches and facilitate the movements among patches (Figure 5). The number, sizes, shapes, and spatial arrangement of habitat patches, as well as the presence of corridors, impose a spatial structure on the species that occupies them.

Several terms contain the word “structure.” The spatial distribution of habitat may be referred to as “patch structure” when applied to a specific habitat type or as “landscape structure” when applied to the spatial pattern of all habitat types in the landscape. The term “population structure” refers to the spatial distribution of breeding groups (i.e., demes) and the rates of exchange of individuals, via emigration and immigration, among these groups. Much of the problem of analyzing population dynamics at the landscape level relates to understanding the influence of landscape (or patch) structure on population structure.

Patches, Matrix, and Corridors

The patch structure of a landscape influences the dynamics of populations living therein because patch structure affects the spatial distribution of individuals and their movements (Saunders *et al.*, 1991). Patch size is one of most important qualities of landscape structure because it is directly related to local population size. Larger patches have a greater abundance of resources and will support a greater N over the long term (i.e., the patch’s carrying capacity), whereas smaller patches support fewer individuals. Immigration and emigration are affected by the distance between patches and the intervening landscape matrix. When patches are far from one another, the chance of successful movement between them is reduced. Dispersing animals can suffer mortality from hazards of predation, starvation, or accident while crossing the unsuitable matrix. The dispersal mechanisms of plant seeds may fail to deliver them to distant patches, and dispersing animals may not find a suitable patch.

Corridors connect patches and facilitate interpatch movements. Similarly, small habitat patches (i.e., habitat fragments) scattered throughout the matrix can act as “stepping stones” to promote movement between large patches. Interpatch distances between these fragments are small, and the habitat fragments provide temporary refuge for the dispersing animal before crossing the next gap. Likewise, these fragments may be too small to support a plant population over the long term, but temporary populations can produce seeds capable of colonizing nearby patches. The effectiveness of corridors and stepping stones for movement can be altered by characteristics of the landscape matrix (Baum *et al.*, 2004; Vergara, 2011).

Figure 5 Schematic diagram of patch–matrix–corridor model. In this example, a centrally located core patch is surrounded by smaller satellite patches. Individuals from the population of the core patch disperse to the satellite patches, which support smaller populations that frequently go extinct. Linear corridors or closely spaced habitat fragments (stepping stones) facilitate movement among patches.

Characteristics of the landscape matrix may facilitate or hinder movement. Habitats in the matrix may be harsh or benign relative to the resource needs of individual species. The matrix may contain barriers to movement. The barriers include natural features such as rivers or mountains and human constructed features such as roadways, agricultural fields, and urban areas. The relative ease or difficulty of movement through the landscape matrix is called its permeability. The spaces between habitat patches, filled by the matrix, are called gaps. A species' ability to move across this space is called its gap-crossing ability. Gap-crossing ability and matrix permeability for a given species in a particular landscape depend on the life-history characteristics, habitat needs, and vagility of the species as well as the matrix itself (Chardon *et al.*, 2003; Baguette and Van Dyck, 2007). For example, a bird can readily fly across 100-m wide plowed agricultural field, but that same field is a barrier to a salamander, which risks predation or death by desiccation during an attempt to cross it.

Landscape Context

The suitability and uses of particular habitat patches may be affected by landscape context. The matrix and landscape-level abundance of similar habitats alter the abundance of a species at the patch scale (Radford and Bennett, 2007). When a given habitat type is abundant in the broader landscape, then it is more likely to see occupancy or visits to small patches (Pearson, 1993; Lewis *et al.*, 2011). This effect has been documented in mobile animals, such as mammals, flying insects, and birds, which readily move between patches. Landscape context affects plant population dynamics by altering pollination services and rates of seed predation (Steffan-Dewenter *et al.*, 2001). The abundance and diversity of habitats in the broader matrix affect the probability that pollinators or seed predators will visit a given patch. Some animal species depend on a variety of habitat types during their lives and the ability to move among them. These species may be especially sensitive to landscape context. For example, some amphibians require wetlands for breeding but then disperse to upland habitats after the breeding season (Pillsbury and Miller, 2008). Such species require different habitat types in different seasons or different parts of their life cycles. Therefore, a mix of patch types that provide supplementary or complementary resources (*sensu* Dunning *et al.*, 1992) must be considered when assessing habitat quality and quantity at patch and landscape scales. By altering rates of immigration and emigration, landscape context can affect the genetic diversity and divergence among populations (Blevins *et al.*, 2011).

Quantifying Landscape Structure and Connectivity

Spatial metrics provide a means of quantifying the spatial arrangement of habitat. The most straightforward metrics focus on the statistical distribution of patch sizes. First, the landscape is classified into suitable versus unsuitable habitat (i.e., a binary landscape), and the areas of suitable patches are tallied. Then the "number of patches," "mean patch size," and "size of the largest patch" are useful for comparing landscapes with similar amounts of habitat but having a different spatial arrangement of habitat. Other metrics can measure more complex aspects of spatial pattern such as the shape of patches. These metrics incorporate a ratio of perimeter-to-area for

patches. Compact shapes, such as circular or square patches, have a lower perimeter-to-area ratio, whereas elongated patches or those with complex shapes have a greater perimeter-to-area ratio. The metric of "contagion" (e.g., Riitters *et al.*, 1996) measures the intermixing of habitat types, which is correlated with number of patches as well as patch size and shape. There are many spatial metrics available, and many are correlated with each other (Hargis *et al.*, 1998). No single metric will measure all of the important aspects of spatial pattern. The best choices will be those metrics that measure the qualities of landscape structure predicted to influence the population processes under study. One of the most important qualities is habitat connectivity, which measures the ease of moving between habitat patches.

Landscape ecologists have developed a variety of metrics for measuring the connectivity of landscapes (Kindlmann and Burel, 2008). These metrics incorporate the interpatch distances, area of habitat at various distances from the focal habitat, and the presence of stepping stones and corridors (Leidner and Haddad, 2011). A proximity index rates the relative amount and distance to suitable habitat for single patches (Gustafson and Parker, 1994). Deciding which among the available metrics is the best choice for any given species remains challenging. Furthermore, connectivity has been treated as both independent and dependent variables in landscape ecology research (Goodwin, 2003). When considered an independent variable, connectivity was considered a structural aspect of the landscape under study. These studies often compared the performance of populations living in landscapes having different patch structures. When treated as a dependent variable, connectivity was a function of various species responses to pattern in the same landscape. A highly mobile species, such as a bird or large mammal, can easily move between patches, but a sedentary organism or nonflying invertebrate will find the same landscape disconnected (or fragmented) if it cannot readily move among patches. Thus, sensitivity to habitat loss and fragmentation depends on species' habitat needs and life-history traits (Driscoll and Weir, 2005; Sutton and Morgan, 2009).

Landscape Structure, Population Viability, and Conservation

Conservation biology naturally considers the effects of landscape structure on population structure and population viability. Therefore, there is a close and complementary connection between the disciplines of Conservation Biology and Landscape Ecology. The conservation of any species depends on the maintenance of viable populations, and the patch structure of landscapes affects population viability at both the patch and landscape level.

Population Viability in Small Patches

Population viability is strongly related to effective population size (N_e) and genetic diversity, two characteristics that are linked. Small populations suffer from demographic stochasticity and reduced genetic diversity. Populations in landscapes

in which small isolated patches predominate show less genetic diversity overall than populations in unfragmented landscapes (e.g., butterfly (Collier *et al.*, 2010) and toad (Allentoft *et al.*, 2009)). Moreover, population sizes in small patches fluctuate to a greater degree because of demographic stochasticity, which is the fluctuation in N_e , birthrates, and death rates through time. They also fluctuate as a result of environmental stochasticity, which is variation in demographic rates from unpredictable events related to factors such as weather. Such fluctuations create a greater chance of extinction and expose the population to loss of diversity because of genetic drift and population bottlenecks.

The viability of populations in small patches is reduced because of limited genetic diversity. Small populations contain less genetic diversity because there are fewer individuals. In addition, genetic drift and inbreeding further reduce genetic diversity over time. Genetic drift is the random change in allele frequencies because of sampling error in the process of mating. Over the long term, drift ultimately leads to the loss of alleles when their frequencies randomly reach zero. Levels of heterozygosity, a common way of measuring genetic diversity, are positively associated with population growth and persistence (Hanski and Saccheri, 2006). Individuals with higher levels of heterozygosity typically have higher survival and reproductive rates than individuals with less heterozygosity (Coltman *et al.*, 1998). This phenomenon is called heterozygote advantage or heterosis. Heterozygosity declines as alleles are lost and the population becomes fixed for one allele. Similarly, inbreeding reduces heterozygosity among offspring when related individuals breed, and inbred populations have a greater chance of extinction (Saccheri *et al.*, 1998). Inbred offspring have lower levels of heterozygosity and have a greater chance of being homozygous for deleterious recessive alleles. This reduced fitness is termed “inbreeding depression.” In small populations, the choice of mates is directly related to N_e , and matings among related individuals will inevitably occur. The primary conclusion is that small populations have lower genetic diversity and stochastic processes of genetic drift, inbreeding, and population bottlenecks will further reduce genetic diversity over time.

The predominance of small patches in fragmented landscapes can affect demography and behaviors. Small populations may suffer reduced population growth rates because of social factors called Allee effects. Allee (1931) suggested that some species have a minimum viable population (MVP) size. Birth and death rates are density-dependent, and recruitment drops to unsustainable levels below a certain N . For example, fertilization rates in flowering plant may depend on visitation rates by pollinating insects, but a minimum density of individual plants is needed to attract the necessary numbers of pollinators (Hackney and McGraw, 2001). When N_e or densities are too low, recruitment rates decline because of low fertilization rates. Likewise, vulnerability to predators can increase in some animal groups. Flock size and herd size are correlated with the ability to detect predators and thereby reduce predation risk for the individual (Lima and Dill, 1990). Allee effects are apparent when survival and reproductive rates are positively correlated with population density and density is below the threshold for density-dependent population regulation (i.e., the carrying capacity). However, care should

be taken not to confuse these effects with the negative effects of small population size such as inbreeding (Stephens *et al.*, 1999). In fragmented landscapes, the small patches may support too few individuals needed to accrue the positive benefits of population size and/or density. For animals, patterns of behaviors such as movements can be altered by habitat fragmentation. For example, Mitrovich *et al.* (2009) found differences in the home range overlap and movements and crowding for the coachwhip (*Masticophis flagellum*), a large snake, in small patches relative to large patches. Movements of large highly mobile mammals may be affected, too. Seasonal movement behaviors of white-tail deer (*Odocoileus virginianus*) varied with the mean size and number of patches in a landscape in the midwestern USA (Grovenburg *et al.*, 2011). Deer in landscapes with many large patches tended to be sedentary residents, whereas those in landscapes with small patches were more likely to be migratory.

The genetic and demographic problems of small populations interact synergistically in a phenomenon referred to as an extinction vortex (Gilpin and Soule, 1986). When N_e falls, genetic diversity is lost because of the phenomena of bottlenecks, drift, and inbreeding. Reduced genetic diversity causes drops in population growth, reducing mean fitness because genetic diversity is correlated with the levels heterozygosity in individuals and the population as a whole. In small populations that have lost a significant amount of genetic diversity, low or negative growth rates further reduce N_e , which results in greater loss of genetic diversity. Moreover, reduced genetic diversity limits the ability of the population to adapt, via natural selection, to changes in its environment. Therefore, small populations are more sensitive to environmental change than large populations having more diversity. This combination of interacting processes eventually threatens the small population with extinction.

What population size qualifies a small population? Although the most accurate answer will depend on the life history of specific species, the “50/500” rule of thumb from conservation biology (Franklin, 1980) provides a useful starting point when detailed life-history information is lacking. This rule states that isolated demes with an effective population size (N_e) greater than 500 will be relatively safe from the dangers of the loss of genetic diversity. These risks progressively increase as N_e declines from 500 toward 50. At $N_e < 50$, all combined forces of the extinction vortex act on the population, and extinction may be inevitable without management intervention. Thus, a $N_e > 50$ is needed for short-term population viability and $N_e > 500$ needed for long-term viability. The “50/500” rule was based on goal of maintaining genetic diversity (Franklin, 1980). Shaffer (1981) outlined the concept known as the minimum viable population. Estimates of a MVP include three parameters: a N_e , a probability of extinction (or persistence), and a specific time period. For example, “An MVP for any given species in any given habitat is the smallest isolated population having a 99% chance of remaining extant for 1000 years despite the foreseeable effects of demographic, environmental, and genetic stochasticity, and natural catastrophes” (Shaffer 1981, p. 132). When incorporating the dangers of demographic and environmental stochasticity, the minimum N_e should be in the range of thousands rather than hundreds (Traill *et al.*, 2010).

Some scientists criticize the notion of general guidelines for MVPs, arguing that the minimum N_e for long-term persistence must be determined on a species-by-species basis (Flather *et al.*, 2011). Population viability and MVP will be affected by the unique combination of species' traits, including its phylogeny, life history, resource needs, habitat availability, population structure and demography, and environmental threats (both natural and human caused) within the context of the landscape where it lives. For landscape-level conservation efforts, it should be more profitable to identify and address the specific causes of population declines (Caughley, 1994) rather than focus on maintaining a minimum number of individuals. Nevertheless, an estimate of MVP can be useful for labeling species as being at risk of extinction, motivating policy makers and managers to take appropriate actions, and setting a target population size for restoration efforts.

Immigration and Rescue Effects

Despite the problems described in the previous section, small populations are frequently observed in nature and seem to persist over the long term. Their persistence can be explained by the fact that these populations are open and connected to other demes in the landscape via the movement of individuals. Population biologists commonly refer to these movements as "immigration" (into) and "emigration" (from) when in reference to a specific deme.

Immigration has several benefits to a small population and some risks. Immigrant individuals can increase genetic diversity if they bring alleles that are absent or rare in the deme. Even infrequent or low levels of immigration are sufficient to restore genetic diversity lost to genetic drift (Slatkin, 1985). Immigrants provide a form of gene flow. The interpatch transport of gametes, such as pollen for flowering plants, is another example of gene flow. Moreover, immigrants provide a form of population growth when local recruitment rates are low (see BIDE model in the section Basic Concepts and Terminology about Population Dynamics). Thus, immigration can periodically rescue a population from the negative effects of demographic stochasticity and loss of genetic diversity, but there are significant risks associated with the movement of individuals. "Outbreeding depression" occurs when immigrants introduce genetic traits that are poorly suited for the local environmental conditions. Offspring expressing these traits will have reduced fitness, and the mean fitness of the population will be lower until natural selection eliminates these traits. If immigration of these traits persists, then the mean fitness and population growth rate will be determined by a balance between immigration and selection. A second risk is the introduction of pathogens and parasites carried by immigrants.

Preserving Habitat at Landscape Level: The SLOSS Debate

Conservation biologists have debated the best strategy for preserving habitat for threatened and endangered species. If the total area of habitat that can be protected is limited, then what is the best scheme for distributing that habitat in space? The essence of this question is whether to protect the same

acreage of habitat in "single large or several small" (i.e., the acronym SLOSS) patches. There are advantages and disadvantages for both choices (Diamond *et al.*, 1976). A single large preserve provides habitat to support the largest possible population. If N_e is sufficiently large, then this choice will avoid the problems of small populations discussed previously. However, the danger of a single habitat patch is that some environmental catastrophe such as a hurricane or fire or an introduced virulent pathogen could extirpate the entire species. If the species is spread across several smaller patches sufficiently separated in space, then the chance of a catastrophic event affecting all of them is less than if they are confined to a single patch. For the "several small" strategy to be viable, the demes of respective patches must be large enough to avoid the extinction vortex, or the populations must be open to movement between patches in order to accrue the benefits of immigration. The movement of immigrants may be natural or facilitated by human management in the form of translocations of individuals.

Land management around preserved patches may include the preservation of corridors to connect patches and facilitate movements among them. Corridors likewise have their relative advantages and disadvantages (Haddad *et al.*, 2011), and their effectiveness depends on the natural history of the target species (Gilbert-Norton *et al.*, 2010). Species that are dispersal-limited or have difficulty crossing the landscape matrix receive the greatest benefits corridors. For animals, corridors of low-quality habitat can enhance movement among habitat patches even if populations cannot persist within the corridor itself (Haddad and Tewksbury, 2005).

Landscape Ecology and Metapopulation Dynamics

Most populations in nature have a patchy distribution because of patchiness of their habitat, and population structure is determined by the exchange of individuals (e.g., immigration and emigration) among patches. If the rates of exchange are high and frequent, such as by a highly mobile species, then there is simply one population occupying multiple patches. If exchanges among patches are very infrequent or nonexistent, then each patch has a distinct and separate population. An intermediate level of exchange would include regular movements among patches by dispersing individuals moving from their natal site to another patch. This amount of exchange characterizes metapopulations.

The dynamics of open populations persisting in a patchy landscape often take the form of a metapopulation. A metapopulation is a network of individual demes connected by the processes of immigration and emigration. Metapopulation dynamics exist when species have demes in discrete habitat patches. Each deme has a finite probability of extinction, but extinction events are not synchronized in time across space. Empty patches are common, but none of them are too isolated to be recolonized from an extant deme. Thus, a metapopulation exhibits turnover in the occupancy of patches that is a function of local extinctions and recolonizations (Hanski, 1999). McCullough (1996) provides examples of metapopulation ecology applied to problems of wildlife conservation.

Metapopulation theory has been an important tool for helping ecologists think about population dynamics in fragmented landscapes, but detecting metapopulations and parameterizing metapopulation models from field data is still challenging (Driscoll, 2007). The incidence function model of (Hanski *et al.*, 1996b) has been one of the most useful because it requires only patch occupancy data. By monitoring how many and which patches are occupied over time, ecologists can relate the probability of occupancy to patch size, shape, and isolation. Alternative techniques include analyses of genetic structure to infer the relative isolation of habitat patches and the frequency of immigration among them (Wang *et al.*, 2008).

Sources and Sinks

In the simplest case of population structure, the size of patches and the quality of habitat contained within them is similar, but this case is likely uncommon in nature. In a metapopulation spread over several habitat patches, variation in population growth rates can exist because of patch-specific differences in habitat quality, interspecific interactions, or other ecological factors. Pulliam (1988) described the situation in which some patches have intrinsic rates of increase ($r = \text{birthrate} - \text{death rate}$) greater than 0 – that is, local birthrates exceed local death rates. These patches were termed “sources” because local population growth will produce an excess of individuals. The local population growth exceeds the patch’s carrying capacity, and these excess individuals must emigrate; if not, then feedbacks from local resource limitation will reduce growth rates. In the same metapopulation, other patches called sinks have $r < 0$ because the local birthrate is less than the death rate. If isolated from other populations, extinction is inevitable for sink populations. However, sinks can persist in the context of a metapopulation because excess individuals from source patches can immigrate into sinks. These sinks receive a demographic subsidy and are able to persist because the sum of (births + immigrants – deaths) ≥ 0 .

The knowledge of source and sink patches is critical for understanding how a particular metapopulation functions. This understanding is important for landscape-level conservation efforts in which choices are made about the protection (or allowing the destruction) of some fraction of the existing patches. If a critical number of the source patches are lost, then the entire metapopulation will collapse (Hanski and Ovaskainen, 2002). Unfortunately, patch occupancy alone is not a reliable indicator of the source/sink status of individual patches. The hard work of estimating demographic rates must be undertaken to fully understand this aspect of population dynamics.

Core and Satellite Model

In conservation planning, the “core and satellite model” of habitat protection has been used at the landscape level (Shen *et al.*, 2008; Snep and Ottburg, 2008). This model envisions critical habitat distributed in patches varying in area and quality. Core patches support the largest N_e and populations that persist through time. Core populations may act as

demographic sources, and their greatest value to the broader metapopulation is to produce emigrants destined for satellite populations (Runge *et al.*, 2006). Small patches located near the periphery of the core patches support small satellite populations that periodically go extinct. Satellite populations depend on immigrants from the core patches to avoid extinction or for recolonization after local extinction. Satellite populations may be demographic sinks or simply have a small N_e that is vulnerable to the problems of small populations.

Landscape Change, Habitat Fragmentation, Edge Effects, and Extinction Debt

Landscape changes, particularly those caused by human land uses, can alter the abundance and connectivity of suitable habitat. Habitat fragmentation results when habitat loss converts a landscape dominated by large connected patches of habitat to one in which habitat exists in small, disconnected fragments. Fragmentation of native habitats is happening on a global scale (Riitters *et al.*, 2000). This phenomenon affects habitat quality as well as its quantity and spatial distribution. Consequentially, fragmentation affects the spatial structure of populations. The effects of fragmentation can be conceptually separated into the effects of (1) reduced patch size and (2) increased patch isolation. The processes of habitat loss and fragmentation often occur concurrently, but Fahrig (2003) argued that their effects need to be considered independently to best understand the consequences of landscape change on populations and communities.

In fragmented landscapes, the effects of small patch size are confounded with edge effects. Small fragments have more edge, which can alter habitat quality. Small habitat patches have a greater edge-to-interior ratio because of simple geometry. As the area of a circle ($\pi \times \text{radius}^2$) decreases, the perimeter of a circle ($2 \times \pi \times \text{radius}$) decreases more slowly. Circles and squares are simple, compact shapes in which length and width are approximately equal. Habitat fragments of elongated and complex shapes have a greater amount of perimeter compared to the area. The patch perimeter or “edge” is the boundary between the habitat of the patch and the landscape matrix, and the ecological conditions at the patch edge can be modified by the conditions in the matrix (Matlack, 1993). For example, consider a forest patch in a matrix of agricultural fields. The edges of forest are drier, warmer, windier, and receive more sunlight than locations deep in the interior of the forest patch. These altered conditions are termed “edge effects” and may extend some distance into the forest patch. Edge effects also include differences in the biotic interactions. For example, predation rates may be greater near edges. The “interior habitat” – sites within the patch but some minimum distance from the patch boundary – is considered free of edge effects. Some species are sensitive to the differences between edges and interiors. So-called “edge-sensitive” or “interior-dependent” species avoid edges or experience lower survival and/or reproductive rates in edges. As fragment size decreases, the edge-to-interior ratio increases; edge-sensitive species have less and less interior habitat for use. Below a particular patch size, interior habitat is absent because edge effects penetrate to all regions of the small patch. Therefore, interior-dependent

species are absent from the smallest patches that are dominated by edge-tolerant species (Banks-Leite *et al.*, 2010). Although the example of forest habitat was discussed here, edge effects also exist for grasslands and other nonforest habitats (Renfrew *et al.*, 2005).

The response of populations to the process of habitat loss and fragmentation may lag behind the changes in habitat quantity and quality. For example, some edge-sensitive species may persist in habitat fragments in spite of the loss of interior habitat. This lag occurs because individuals survive in small patches but long-term recruitment rates drop below mortality rates. Thus, small patches are occupied and some reproduction may be occurring, but not enough for long-term population persistence. In addition, the metapopulation dynamics may be disrupted by the overall loss of participating patches or the loss of a critical patch, and the metapopulation collapses (Hanski *et al.*, 1996a). Eventually, these species will go extinct in this landscape, but extinction is delayed by the presence of long-lived individuals and some low levels of reproduction. This delay is termed “extinction debt” (Hanski and Ovaskainen, 2002; Honnay *et al.*, 2005), and it depends on the life history of species affected by habitat fragmentation (Piqueray *et al.*, 2011). Krauss *et al.* (2010) reviewed data for a variety of species living in fragmented grasslands of Europe. They found that long-lived perennial plant species were more likely to exhibit extinction debt than short-lived, mobile species such as butterflies. For species exhibiting extinction debt, their distribution on the landscape is better explained by past habitat patterns than by the distribution and quality of habitat in the contemporary landscape.

Environmental Gradients and Habitat Heterogeneity at Multiple Scales

The concept of source and sink populations (Pulliam, 1988) raised awareness of how variation in demographic performance among patches affects the occupancy of individual patches as well as the landscape-wide distribution of a population. The spatial arrangement of patches is important because sink patches may persist only if they are within the dispersal window of at least one demographic source (Foppen *et al.*, 2000). In the original models of source and sink metapopulations, within-patch conditions were considered homogeneous, but this situation is seldom typical in real landscapes. Spatial heterogeneity within patches may affect demographic rates and population dynamics at fine scales.

For large patches, spatial heterogeneity in habitat quality may create source-sink dynamics among sites within the patch. Environmental heterogeneity can create a mosaic of sites having higher and lower rates of survival, reproduction, and recruitment (Meekins and McCarthy, 2001). Within-patch heterogeneity can be especially high when patches are defined by a coarse-level criterion, such as land-cover type, and fine-scale heterogeneity is ignored. Fine-scale heterogeneity in temperature, moisture, soil nutrients, etc. may be correlated with occurrence of individuals (Palmer, 1990; Fraterrigo *et al.*, 2006) and demographic rates (Meekins and McCarthy, 2001). If habitat quality is strongly correlated with fine-scale edaphic conditions (or some other measure of resource abundance for

such food availability), then these conditions may be used to estimate the demographic potential of a given site (Seydack *et al.*, 2000; Ecke *et al.*, 2002; Gonzalez-Megias *et al.*, 2005; Flinn, 2007). Although not separated into discrete patches, source-sink dynamics can occur among the sites within patches. The demographic rates associated with an entire patch will be a function of the average habitat quality of its embedded sites. Landscape ecologists, with their appreciation for issues of scale, are well-equipped to study the relative effects of within-patch, among-patch, and landscape heterogeneity on population dynamics.

Changing patterns of biodiversity in changing landscapes illustrate how spatial patterns at different scales interact with population processes. In portions of Europe and North America, forests are expanding following agricultural abandonment. New forest patches are developing from abandoned farmland via the process of secondary succession; this new habitat is also called postagricultural forest. The spatial arrangement of old forest patches is of great importance for native herbaceous plant species that depend on forest habitats. At the landscape scale, the abundance and proximity of “ancient forests” (not cleared for agriculture) is correlated with the patterns of plant diversity among recovering forest patches (Matlack, 1994a, b). The ancient forests preserved a pool of forest plant species during the time period of heavy agricultural use in the landscape (Pearson *et al.*, 1998). During the period of recovery after the peak of agriculture, these species are able to disperse from the ancient forests to the new forest patches. Moreover, life-history traits influence the establishment and persistence of populations (Vellend, 2003; Flinn and Vellend, 2005) in particular patches. Verheyen *et al.* (2003) studied the distribution of forest herbaceous plant species in these postagricultural forests and their landscapes. They found that recovery after disturbance is a two-stage process in which the dispersal and colonizing ability of a species is initially most important in establishing populations in new forest patches. Next, after a species had colonized a new forest patch, habitat quality and niche specialization of the species influenced abundance and persistence within patches (also Pearson and Fraterrigo, 2011). The distribution of dispersal limited plant species was not correlated with habitat quality at the landscape scale because these species simply could not reach isolated forest patches. In other words, habitat fragmentation negated any effects of varying habitat quality for these postagricultural forests in the initial phase of recovery. Habitat quality became important only if and when a species reached a patch. This process takes many years to play out and will affect forest biodiversity for a century or more of recovery (Vellend *et al.*, 2007).

Continuous Habitat Variability in Landscapes

The patch-matrix-corridor approach to characterizing spatial pattern is useful for landscapes in which patches exist as discrete readily identifiable units, and there are greater differences among patches than within them. However, in many landscapes, habitat variation occurs along environmental gradients that change relatively slowly across space (Figure 6). In such a landscape, drawing a definite boundary to denote habitat

Figure 6 Map of predicted soil moisture as an example of continuous variation in habitat quality. Soil moisture is influenced by topography shown by 10-m contour lines as well as slope, aspect, and surrounding landforms. Drier sites are found on ridges and peaks, whereas wetter sites are located in ravines and valleys. This map was developed using a digital elevation model to calculate a topographic relative moisture index (Parker, 1982). (Reproduced with permission from Simon SA, Collins TK, Kauffman GL, McNab WH, and Ulrey CJ (2005) *Ecological zones in the Southern Appalachians: First Approximation*. Asheville, NC: US Department of Agriculture, Southern Research Station. Forest Service Research Paper SRS-41). Map shows 50-m grid cells.

patches is nearly impossible because suitability varies in a complex and continuous manner across space. In mountainous landscapes, topography creates gradients in temperature, moisture, and light related to elevation, aspect, slope, and terrain shape (Figure 6). Instead of maps of discrete patches of suitable and unsuitable habitat, these landscapes are best represented by maps showing continuous variation in habitat quality (Thompson *et al.*, 2006; Franklin, 2009).

Quantifying the spatial pattern of habitats in these landscapes is challenging (Dorner *et al.*, 2002). The statistical characteristics of this continuous variation can be quantified using a range of statistical techniques including blocking, spectral analysis, measures of spatial autocorrelation (Turner *et al.*, 1991), or surface metrics (McGarigal *et al.*, 2009). Patterns of habitat heterogeneity can change between fine and coarse scales, and these analyses can identify the particular spatial scale(s) in which spatial pattern and population processes are linked (Fortin and Dale, 2005). To be useful, the analysis should be approached from an organism-based perspective; that is, landscape structure can be understood by

relating environmental gradients to the tolerances and resource needs of individual species (Cushman *et al.*, 2010) and to population processes such as dispersal ability and sizes of home ranges. The influence of environmental gradients in determining species distributions and community composition has long been recognized by the ecologists. However, the theory and analytical techniques for studying populations in these types of landscapes is still under development.

Landscape Structure and Interspecific Interactions

Interspecific interactions are important determinants of population dynamics, and landscape structure can influence these interactions. All species interact with predators, parasites, competitors, and so on as the biotic portion of their environment. In breeding birds of forests, nest predation rates are affected by both landscape-level and within-patch habitat patterns (Lloyd *et al.*, 2005). Predation rates increase as patch sizes decline and the landscape-wide abundance of nonforest

Figure 7 Illustration of a landscape as a shifting mosaic of sites in different stages of recovery from disturbance. In the schematic (a), sites fully recover from disturbance after 60 years of recovery. A landscape in the Pisgah National Forest in North Carolina (b) is a mosaic of forest stands of various ages as measured by time since the year of stand origin. This pattern is a consequence of natural disturbances and human land uses such as timber management.

habitats increases. Moreover, landscape structure influences the movement patterns of different predator species so that the risk of encountering a specific predator species depends on the precise location in the landscape (Bergin *et al.*, 2000). Conversely, spatial complexity can promote coexistence between predators and prey. “Refugia” are habitats (or microhabitats) where preys are relatively safe from predators. When predators are abundant, refugia prevent them from driving their prey to extinction.

Spatial heterogeneity is one of the principal explanations for the coexistence of competing species (Amarasekare, 2003) in community ecology. Coexistence can be achieved by niche partitioning when species specialize on different habitats or resources. Habitat heterogeneity within and among patches promotes coexistence. Spatial structure and heterogeneity through time are also necessary for the coexistence by the competition–colonization trade-off (Tilman, 1994). In this mechanism, competing species differ in their competitive abilities and ability to colonize new habitat patches. The superior competitors have low colonizing abilities, and the better colonizers are poor competitors. Disturbance periodically kills off local populations of the superior competitor, and for a brief time those sites or patches are empty. The superior

colonizer (but poor competitor) quickly occupies the empty sites and holds them until the superior competitor arrives. Regular, localized disturbances permit coexistence by continually providing habitat for the poor competitor (e.g., Debout *et al.*, 2009). Coexistence is possible when the landscape is a shifting mosaic of disturbed patches and sites at different stages of recovery from prior disturbances (Figure 7). Disturbance and its effects on landscape structure through time are a recurring research theme in landscape ecology.

Summary

Landscape ecology is concerned with the causes and consequences of spatial pattern in nature at multiple spatial scales. Spatial pattern in habitats and resources influences the growth, persistence, and decline of populations. The patch–matrix–corridor model of describing spatial heterogeneity is a useful conceptual model that is directly applicable to populations. Species frequently exhibit a patchy distribution in landscapes as a function of the spatial arrangement of their habitats. This landscape-level pattern (i.e., the landscape structure) determines how populations are organized in

local breeding groups and how frequently individuals move between these groups. This population structure in turn affects population dynamics. Landscape structure, in combination with life-history traits of a species, determines whether that species exists as a single large population, as a metapopulation of demes connected by movement of individuals, or as a collection of separate isolated populations. An understanding of population structure reveals the conservation challenges facing many species. In landscapes in which habitat is highly fragmented, isolated populations in small patches face a number of problems ranging from loss of genetic diversity to edge effects. Thus, the landscape ecology of populations is related to conservation. Some landscapes exhibit continuous variation in habitat quality, and the patch–matrix–corridor model is not directly applicable. Techniques for describing habitat heterogeneity at multiple scales are available, but understanding how this type of variation affects population dynamics is more challenging.

Landscape Epidemiology

Felicia Keesing, Bard College, Annandale-on-Hudson, NY, USA

Landscape epidemiology, broadly defined, is the study of spatial variation in disease risk or incidence (Lambin *et al.*, 2010; Ostfeld *et al.*, 2005). The roots of landscape epidemiology stretch back to John Snow's mapping of cholera incidence in London in the 1850s, work which founded the modern science of epidemiology. Snow created maps of the distribution of cholera cases and found that the cases were clustered around a particular water source – the Broad Street pump. When the pump was closed, the number of cholera cases rapidly declined.

Almost 100 years later, a Russian scientist, Evgenii Pavlovsky, coined the term “landscape epidemiology” and extended Snow's concept (Pavlovsky, 1966). Like Snow, Pavlovsky recognized that infectious diseases occur in specific environmental contexts because the distributions of the organisms involved in the transmission of the pathogen are limited to some extent by environmental conditions. Knowledge of these environmental constraints can permit us to characterize, predict, and manage the risk of transmission, just as Snow did. Pavlovsky's innovation was to extend Snow's ideas to the diseases transmitted to humans less directly than cholera.

Cholera is caused by a bacterium, *Vibrio cholerae*, which causes illness when it is ingested by humans. One of the major symptoms of infection with the bacterium is diarrhea, which releases bacteria back into the environment and potentially back to humans through contaminated water. Cholera, then, is a disease directly involving two species – humans and *V. cholerae*. In contrast, “zoonotic diseases” are caused by pathogens that are transmitted to humans from another animal. Hantavirus pulmonary syndrome (HPS) is a notable example. HPS is caused by infection with one of many types of hantaviruses, which are typically shed in the urine or feces of an infected animal, such as a wild rodent; the virus particles can then be inhaled by a human victim. Thus, three species are involved and the disease can only occur where humans, a particular rodent species, and the pathogen coexist in the environment. Some zoonotic diseases are transmitted among hosts by vectors, such as mosquitoes, ticks, or biting flies. These “vector-borne zoonoses” involve at least four species – a human, the pathogen, a wildlife host, and the vector. Pavlovsky was particularly interested in vector-borne zoonotic diseases, how their current and future ranges are shaped by environmental factors, and how the knowledge of these relationships could be used to reduce transmission to humans.

Decades after Pavlovsky, landscape epidemiology is being widely used to ask questions about the spread of pathogens. For example, how does landscape fragmentation influence pathogen spread? At what spatial scales does the presence of resistant species provide a buffer against the spread of pathogens? How can landscapes be designed to control the spread of diseases of humans, wild and domesticated animals, and plants?

The modern study of landscape epidemiology can be divided into two broad research foci. In one approach,

investigators study the effects of actual geographic entities on diseases (i.e., map-based approaches); in the other, they utilize abstract geographic entities (i.e., modeling-based approaches). Map-based approaches can be further divided into those that generate an understanding of how spatial patterns of disease change dynamically through time, and those that consider static patterns in disease based on the distribution of hosts, vectors, or disease incidence.

Dynamic Map-Based Approaches: Analyzing Patterns Through Space and Time

Many epidemiologists are interested in understanding the processes that cause spatial patterns of disease risk or incidence to change through time. To address this issue, researchers incorporate dynamic processes (e.g., demographic, genetic, or behavioral changes) into spatiotemporal models to explain or predict epidemiological patterns. Dynamic approaches are exemplified by a recent study of the spatiotemporal patterns of human infection with rotavirus, a pathogen that infects people worldwide (Pitzer *et al.*, 2010). Data collected for 11 years on patients with rotavirus were used to develop alternative models of epidemic patterns in USA. The model with the best fit to the data incorporated differences in birth rates among states, and this model explained geographic shifts in outbreaks over time – states with the highest birth rates had earlier seasonal onset of rotavirus epidemics.

Dynamic spatiotemporal analyses require relatively large amounts of data both in space and in time (but see Tildesley *et al.*, 2010). Data of this quality tend to be available for diseases that are well-known infections of people, such as measles and influenza, or of their domesticated plants and animals. For these types of diseases, sophisticated mathematical analyses can provide useful guidance for the development of prevention strategies. Results of such studies can also reveal patterns applicable to less familiar diseases. For example, an analysis of data from 14 years and 850,000 infections with dengue hemorrhagic fever (DHF) in Thailand showed that cases moved in a traveling wave emanating from Bangkok, the largest city in the country, out to the countryside at 150 km per month (Cummings *et al.*, 2004). This information could guide interventions for DHF, and also for less well-documented infections in the region.

Static Map-Based Approaches: Using Current Distributions to Predict the Future

In contrast to the dynamic approaches, static approaches require fewer data and less sophisticated mathematical models. They are useful for characterizing spatial variation in current risk and for predicting the underlying causes of that variation.

Figure 1 Conceptual model of the relationship between environmental factors that influence disease and observed incidence of that disease in humans. Underlying environmental factors (e.g., temperature, precipitation, land use, and soil type) can influence the distribution of vectors and hosts for a particular disease. These distributions influence the risk to humans of coming into contact with the pathogen that causes the disease. Variation in this risk is one factor that determines the actual number of cases of human disease. Because of differences in surveillance and reporting, the observed incidence in humans is likely to be a subset of actual cases. Modified from Ostfeld RS, Glass GE, and Keesing F (2005) Spatial epidemiology: An emerging (or re-emerging) discipline. *Trends in Ecology & Evolution* 20: 328–336.

The typical approach is to create a map of the distribution of a host or vector and then to use remote-sensing data and geographic information systems to identify underlying geographic variables that correlate with that distribution (Figure 1). Once the variables that are most strongly correlated with the distribution are identified, the values of these variables can be projected onto maps outside the spatial limits of the original distribution. Alternatively, the values of these variables can be projected forward in time and used to predict future distributions.

This approach is typified by a study of the distribution of the incidence of West Nile Virus (WNV) encephalitis shortly after its emergence in the New York City area (Brownstein *et al.*, 2002). WNV encephalitis is caused by WNV, which is transmitted to hosts through the bite of any of several species of infected mosquitoes. In this study, human cases of the disease were mapped and found to be correlated with the “normalized difference vegetation index” (NDVI). NDVI is an index of the amount of green vegetation in an area and can be readily obtained from satellite images using remote-sensing technology. The range of NDVI values correlated with human cases was projected onto areas where human cases had not yet been detected. The ability of the variables to predict future incidence in humans was tested by comparing NDVI values to

data on the locations of infected mosquitoes; 72% of locations with infected mosquitoes were identified as high risk based on their NDVI values. With this validation, NDVI values could then be used to predict likely areas for future human cases.

Using Data on Incidence

The use of disease incidence data to construct risk maps, as in the WNV example, has several advantages. Incidence data are often more easily obtainable than data on hosts or vectors. Incidence data also integrate a suite of environmental risk factors; if a case occurs, the environmental requirements for host, pathogen, and vector (if relevant) must be met. However, incidence data also present several challenges. First, incidence might not be correlated with risk. This would be the case if, for example, preventative measures (e.g., bednets and repellents) were implemented to reduce the incidence in areas of risk. In such cases, the use of incidence data would lead to an underestimation of areas of potential risk. Incidence data might also be decoupled from risk if the disease system is not in equilibrium, for example, if it is emerging in a new area. In the WNV example, most cases were restricted to a narrow geographic region near the presumed area of emergence of the virus in USA (Brownstein *et al.*, 2002). As a result, only this

area was assessed for fit with predictor variables. If a wider geographic region had been used, the analysis might have identified incorrect predictor variables. Another challenge of using incidence data is that reporting standards are often not uniform across geographic boundaries.

Using Data on Hosts

An alternative to using data on cases of a disease is to use data on the distribution of hosts for the pathogen that causes it. A good example of this type of approach comes from research on appropriate locations for the reintroduction of wild boars (*Sus scrofa*) to Denmark (Fernández *et al.*, 2006). The plan to reintroduce boars is a response to conservation concerns following their extirpation, but the planned reintroduction also raises concerns about possible economic consequences. Boars are reservoirs for the virus that causes classical swine fever, which can be transmitted from wild boars to pigs at commercial pig farms. The researchers predicted boar population sizes at candidate reintroduction sites based on demographic parameters and habitat suitability and then estimated risk to pigs based on the number and types of farms in the area. Based on the underlying model of boar populations, many of the sites that were most suitable for boar reintroduction also created high risk for viral transmission to pigs. Successful reintroduction, therefore, was predicted to require active efforts to minimize contacts between boars and pigs throughout the areas of successful reintroduction.

Host-based approaches have also been used for plant diseases. For example, a recent study assessed the consequences of land-use changes in California forests on the abundance of hosts for *Phytophthora ramorum*, a fungus that causes Sudden Oak Death (Meentemeyer *et al.*, 2011). Aerial images of the study areas from 1942 were compared with images from 2000 to determine changes in suitable habitat for known host plants. Areas that had experienced the greatest increase in woodland (host) habitat over that time period were found to have higher current incidence of disease.

Using Data on Vectors

For vector-borne diseases, data on the distribution of vectors can be used to approximate disease risk. The underlying principle behind this approach is that the presence of the vector is necessary for transmission to take place. However, a major limitation of this approach is that the presence of the vector is not sufficient for transmission – the pathogen must be present as well. Thus, vector mapping can determine areas of no risk (because vectors are absent) and of potential risk (because vectors are present but not necessarily infected), but this method alone cannot determine actual risk.

Many studies of this type are concerned only with the presence or absence of the vector at a given location. A recent investigation of the distribution of blacklegged ticks (*Ixodes scapularis*), which are the vector for a suite of zoonotic diseases, tracked not only the presence of ticks at a suite of locations but also their abundance (Diuk-Wasser *et al.*, 2010). Based on a statistical model parameterized by climatic and habitat characteristics, the best predictors of tick abundance

were altitude, vapor pressure deficit, and the presence of nearby sites with abundant ticks. The model was tested by comparing its predictions to sites where tick abundance was known but had not been included in the development of the model. Based on strong concordance between predicted and observed abundance, the model could be used to predict areas that could see growth in tick populations because they contain habitat highly suitable for ticks, but currently do not harbor abundant tick populations.

All three of these approaches – incidence based, host based, and vector based – share a common limitation. All use patterns to determine correlations with predictor variables, but correlations cannot establish cause-and-effect relationships. Nevertheless, these approaches can allow rapid assessment of potential risk.

Mapless Approaches

Abstract spatial models of disease incidence or risk do not rely on explicit spatial placement on maps of entities involved in transmission. These models can be useful for describing patterns, developing theory, and generating predictions that can be tested in real landscapes. There are four main approaches – patch models, distance-transmission models, multigroup models, and network models (Riley, 2007). These models vary in the degree of resolution with which they track transmission events. In patch models, individuals occur in patches (e.g., towns) and patches are connected to other patches to varying degrees. All individuals within a patch are assumed to have the same transmission status – for example, all individuals in the patch are susceptible or all are infected. At the other extreme, in network models, each individual is connected to other individuals to varying degrees, and transmission can only occur between connected individuals.

The choice of the appropriate modeling approach depends largely on the characteristics of the underlying disease system being modeled. For example, a respiratory pathogen that requires close contact between individuals for transmission to occur might best be modeled by a network that takes account of frequency of contact even within a household. In contrast, for a highly contagious pathogen, a patch model might be sufficient because membership in a patch would be likely to result in transmission.

Frontiers in Landscape Epidemiology

Several directions seem particularly promising for the future study of landscape epidemiology. First, there is still much to learn about how the configuration and composition of landscape elements influence diseases. Patch size, shape, and connectivity, for example, have been shown to influence many ecological processes in the study of “landscape ecology,” but their effects on disease are less well studied. A major research question in landscape epidemiology is how and when local biotic and abiotic conditions predict disease risk and incidence, and how and when the larger landscape context overrides these local influences (Ostfeld *et al.*, 2005).

Landscape epidemiology is also likely to benefit from “landscape genetics,” which takes advantage of burgeoning access to genetic information (Biek and Real, 2010). Knowledge of the genetics of hosts and pathogens through space and time permits a new level of detail in studying disease patterns. For example, amphibian populations are being devastated worldwide by a chytrid fungus, *Batrachochytrium dendrobatidis*. Genetic analyses of *B. dendrobatidis* imply a single genetic origin of the fungus, which has since spread globally. This suggests that human dispersal of the pathogen is a more likely explanation for its spread than factors related solely to amphibian ecology (James *et al.*, 2009; Biek and Real, 2010). Detailed genetic information can also be used to reveal spatial patterns and processes in dynamic analyses. A study utilizing more than 1000 complete genomes of human influenza virus revealed that variants in temperate areas are more closely related to those in other temperate areas in any given year than they are to the variant from the same place the previous year (Rambaut *et al.*, 2009). This suggests a common tropical source that seeds temperate regions each year. A recent study of the spread of chronic wasting disease (CWD) in deer provides a final example of the potential of landscape genetic approaches. Researchers used genetic markers to estimate gene flow among deer populations in Wisconsin and then determined geographic barriers preventing gene flow (Blanchong *et al.*, 2009). The area connected by the least gene flow also had the lowest incidence of CWD, suggesting that (1) the same geographic barrier preventing gene flow (a river) also prevented contact that led to transmission, and (2) host gene flow could be a useful index by which the potential for spatial spread of infections is measured, especially when infection itself is hard to detect.

A final new development comes from “geographic profiling,” an approach that was originally developed for use in criminology. As applied to landscape epidemiology, this statistical technique relies on two underlying assumptions: (1) transmission declines with distance from an infected host (“distance-decay”), and (2) if suitable habitats are distributed randomly in the landscape, habitats suitable for transmission are more abundant further from the infected host (“buffer zone”) (Le Comber *et al.*, 2011). Using these two assumptions, a geoprofile is created, characterizing possible locations of the infected host or vector within the study area. In a study of malaria in Cairo, Egypt in 2001–2004, a geoprofile was created from human cases. The profile correctly identified six of eight pools with breeding mosquito vectors and was more effective than other techniques that rely on case data to make spatial inferences. Geoprofiling may thus be a productive way to identify important disease agents rapidly from relatively little data.

Summary

Pathogen transmission is an inherently spatial process, requiring contact in space and time between an uninfected host and an infectious source (Killilea *et al.*, 2008). As a result, pathogen transmission can be studied in one direction by identifying where (and perhaps when) the elements necessary for transmission cooccur and then predicting the likely future

incidence. In the other direction, data on the incidence of a disease can be used to work backward to predict where (and perhaps when) the elements for transmission coincided.

Because all pathogen transmission has a spatial component, landscape epidemiology could, in principle, encompass virtually all studies of transmission. A more restrictive – and potentially more useful – definition might focus on questions of scale, as has been done for the field of “landscape ecology.” At what scale, for example, are the processes affecting transmission determined? Do the processes that affect transmission patterns occur at the same scale at which the patterns are detected, or at a different one? It is in the pursuit of answers to questions like these that the full richness of landscape epidemiology will be achieved.

Glossary

Carbon (or nutrient)-accumulation rate The rate at which carbon or nutrients, such as nitrogen and phosphorus, accrue in biomass and soils.

Deforestation The most intense form of timber extraction, wherein forests are converted for another land use either permanently or for a long term.

Landscape legacy The long-term impact of historical events on ecosystem structure, composition, or function.

Natural disturbances Any relatively discrete event in time that is not directly caused by humans; disrupts ecosystem, community, or population structure; and changes resources, substrate availability, or the physical environment (White and Pickett, 1985).

Nitrification The step in the nitrogen cycle wherein ammonia is oxidized and converted to nitrite and then oxidized again to form nitrate.

Plow horizon The homogenous soil layer, typically at 0–20 cm depth, that results from plowing. Designated as the “Ap” horizon in soil morphology.

Selective logging A less intense form of timber extraction involving removal of select trees, often based on species, size, or age class. The forest canopy is typically maintained under this process.

Site history The collection of past events involving natural disturbance or land use conversion at a given site.

Soil organic matter (SOM) depletion The loss of organic matter from the soil. The main constituent of SOM is soil organic carbon. Consequently, this measurement relates directly to soil organic carbon loss and storage.

Introduction

At the start of the twenty-first century, appreciation for the importance of site history was emerging, yet most ecological studies tended to focus on the here and now, and many ecologists were unconcerned with the events that occurred in the distant past. There was a general perception that site history was unimportant for understanding the patterns and processes of modern ecosystems (Foster *et al.*, 2003). However, over the past two decades, ecologists have come to recognize that historical events can have lasting impacts on ecosystem structure, composition, and function. Indeed, many studies now show that site history can explain a substantial amount of the variation in contemporary ecological patterns and processes in both terrestrial and aquatic ecosystems. The strong, lingering effects of historical events on ecosystems are known as landscape legacies.

The duration of such impacts can be surprisingly long, particularly for ecosystem properties that are physically affected by past events. Soil and vegetation communities, as well as the processes they influence (e.g., nutrient cycling and primary production), often retain the imprints of past events for decades to centuries. In several cases, recovery from past events has not yet been observed, thereby leading the scientists to ask whether some ecological changes might persist indefinitely (Peterken and Game, 1984). In areas of northeastern France deforested during the Roman occupation and farmed during AD 50–250, species richness and plant communities of modern forests, as well as the chemical and structural properties of soil, still varied for more than 1500 years later with the intensity of former agriculture (Dupouey *et al.*, 2002). Similarly, modern forest composition, microtopography, soil texture, and the lake and wetland sediment deposits are strongly associated with the Mayan practice of deforestation in

AD 700–900 (Turner *et al.*, 2003). Changes brought about by past events can also act indirectly to produce lasting alterations in animal assemblages. In southeastern USA, fish and stream invertebrate communities are less diverse today because historical agriculture has persistently increased the amount of sediments in nearby streams (Harding *et al.*, 1998). Examples such as these have called into question the long-standing assumptions about trajectories of ecosystem recovery and compelled ecologists and managers to rethink of traditional concepts about natural or reference ecosystem states, as well as the controls on species distribution and abundance (Foster *et al.*, 2003; Flinn and Vellend, 2005). The knowledge gained from the studies of landscape legacies could, therefore, be important for directing management policies and more accurately predicting how biodiversity will change in the future.

Drivers of Landscape Legacies

Land Use

Human land use is a primary driver of landscape legacies. Humans have long used the land in ways that would modify the native ecosystems, and a growing body of evidence demonstrates that these changes can persist even long after human activities cease. Agriculture is the quintessential example, having been practiced in the form of cultivation and livestock husbandry since plants and animals were domesticated 10,000 years ago (Diamond, 2002). Although agricultural land use is expanding in some regions, other regions have experienced widespread agricultural abandonment (Ramankutty and Foley, 1999). For example, many modern forests in Western Europe and eastern North America existed as farms or pastures during the nineteenth and twentieth centuries (Rackham,

1980; Peterken and Game, 1984; Foster, 1992; Verheyen *et al.*, 1999).

Despite long periods without additional disturbance, most lands with an agricultural history have characteristics distinct from those of lands without a similar disturbance history. Such agricultural legacies have been observed in a broad range of native ecosystems, including temperate mixed and deciduous forests in Europe and eastern North America (Motzkin *et al.*, 1996; Foster *et al.*, 1998; Compton and Boone, 2000; Richter *et al.*, 2000; Hermy and Verheyen, 2007), grasslands and arid lands in the central and western USA (Burke *et al.*, 1995; Coffin *et al.*, 1996; Lewis *et al.*, 2006), and in tropical forests (McGrath *et al.*, 2001; Thompson *et al.*, 2002; Turner *et al.*, 2003). Although agricultural legacies are pervasive, their longevity and magnitude vary because the intensity and duration of agriculture, and specific management practices attending to agriculture, can differ widely (Coffin *et al.*, 1996; Compton *et al.*, 1998; McLauchlan, 2006). Empirical studies and meta-analyses demonstrate that the effects of cultivation and pasturing on soil carbon and nitrogen pools, for example, can vary markedly depending on farm-residue management, crop rotation, and tillage practices (Fearnside and Barbosa, 1998; Murty *et al.*, 2002). Despite this variation, cultivated lands consistently show more persistent and profound legacies than pastured lands due to the high, sustained intensity of cropping (Compton and Boone, 2000; McGrath *et al.*, 2001; Gerhardt and Foster, 2002; Brown and Boutin, 2009).

Timber extraction can also generate landscape legacies. These legacies tend to be smaller in magnitude and of shorter duration than those attending agriculture, but understanding the legacies of timber extraction is vital due to global importance and long history (spanning for more than two millennia) of this practice (Williams, 2000; FAO, 2006; Hansen *et al.*, 2010). Timber extraction, like agriculture, is practiced with varying intensity. Deforestation (or clearcutting) is the most detrimental of such practices, characterized by wholesale forest clearance and substantial soil disturbance. Selective logging represents the opposite extreme and is characterized by the removal of a few individuals (often economically desirable species) and minimal soil disturbance. The extent of land conversion can be substantial under practice (Asner *et al.*, 2005), but selective logging is generally thought to have less appreciable and short-term effects compared with deforestation (Williams, 1990). Indeed, in studies examining the impacts of historical land use, former selectively logged stands are frequently used to characterize reference ecological conditions when undisturbed stands are unavailable.

Forest loss associated with deforestation has occurred heterogeneously over the past 2000 years. Europe and Asia experienced significant deforestation during both pre-1650 and from 1750 to 1849 but are now undergoing afforestation in many parts (Williams, 1990; FAO, 2006). Extensive forest clearance in eastern North America began in the early nineteenth century and has been followed by rapid afforestation. Today, the regions suffering the largest losses due to deforestation are in South America and Africa, where forests are being cleared for cropping or livestock grazing (FAO, 2006). Tropical forest recovery is of particular concern because of its potential to impact global carbon and nutrient budgets and plant and animal biodiversity.

Detecting land-use legacies is often challenging because of preexisting differences in site conditions. From a statistical standpoint, variation in the initial conditions of sites with similar histories may be large enough to swamp variation associated with previous land use. Legacies may still be present within a given site but may be statistically undetectable because the signal is weak relative to that produced by the physical gradients. Relying solely on mean values to evaluate the effects of land-use history may therefore be misleading, and patterns of spatial heterogeneity or structure may yield a more comprehensive depiction of enduring changes (Fratterigo *et al.*, 2005, 2006b). Initial site conditions can also confound detection of historical land-use effects by biasing land use. For example, sites with good drainage were favored for cultivation relative to sites with poor drainage, which were avoided. As a result, ecological patterns on historically cultivated and uncultivated lands may not be comparable. Approaches for dealing with this problem include pairing or blocking sites with different histories to control for environmental variation.

Natural Disturbance

Natural disturbances can also leave legacies that persist for decades to centuries. For example, research conducted across a chronosequence of burned lodgepole pine stands in Yellowstone National Park indicates that large, stand-replacing fires contribute to variation in stand density and growth rate for nearly two centuries (Kashian *et al.*, 2005a, 2005b). Previous disturbance history can also influence the severity of future disturbances. In the subalpine forests of western USA, spruce beetle outbreaks appear to reduce the susceptibility of forest stands to low-severity fires by elevating forest floor moisture (Kulakowski *et al.*, 2003), whereas previous blow downs result in more severe burns decades later (Kulakowski and Veblen, 2007).

Despite the potential for natural disturbances to generate considerable variation in ecological patterns and processes, evidence suggests that ensuing dynamics will be constrained by patterns initiated by past land use. In tropical forests of Puerto Rico, successional vegetation trajectories following hurricanes, landslides, and local treefalls correspond more to land use in the nineteenth and early twentieth centuries than to the severity of recent natural disturbances (Thompson *et al.*, 2002). Similarly, patterns of plant and soil variation on New England sand plains closely relate to historic variation in nineteenth-century agriculture, and repeated episodes of fire have had little effect (Motzkin *et al.*, 1996; Eberhardt *et al.*, 2003). These studies reinforce the need to consider historical context when interpreting disturbance effects.

Legacies in Plant Communities

What are the dominant legacies of human land use and natural disturbance on plant communities, and what factors influence them? Research conducted in temperate forest ecosystems demonstrates that previous land use strongly controls the species composition of contemporary forests

(Foster, 1992; Motzkin *et al.*, 1996; Hermy and Verheyen, 2007). Overstory composition of forests in eastern and mid-western USA has shifted from long-lived and shade-tolerant species to more rapidly growing and short-lived species as a result of historical agriculture and logging (Foster *et al.*, 1998; Rhemtulla *et al.*, 2009). In southern New England, for example, primary forests are dominated by *Acer saccharum*, *Acer rubrum*, *Fagus grandifolia*, and *Tsuga canadensis*, whereas secondary forests abandoned from agriculture a century ago are dominated by *A. rubrum* and *Pinus strobus* (Flinn and Marks, 2007). The species attaining dominance in secondary forests are generally those that sprout effectively or aggressively invade cleared or cultivated lands (Eberhardt *et al.*, 2003; Foster *et al.*, 2003). Studies from tropical and temperate forests demonstrate that non-native invaders, in particular, can quickly become dominant in anthropogenically disturbed stands and persistently preclude re-establishment of native species (Brown and Gurevitch, 2004; DeGasperis and Motzkin, 2007). Selection for species with disturbance-adapted traits has also contributed to the homogenization of overstory species composition at a regional scale (Schulte *et al.*, 2007; Rhemtulla *et al.*, 2009). Such is the case in New England, a region characterized by a history of agriculture, logging, and reforestation (Foster *et al.*, 1998). Paleoecological data indicate that pre-European patterns of forest vegetation that corresponded with differences in climate, substrate, and fire regime have been obscured by European settlement, which has produced a more homogenous regional flora (Fuller *et al.*, 1998). Similarly, the density, age, and size structures of contemporary forests with a history of anthropogenic or intensive natural disturbance often have a more uniform distribution relative to old-growth forests (Goodale and Aber, 2001; Kashian *et al.*, 2005b; Rhemtulla *et al.*, 2009).

Long-term changes in overstory composition and structure can result in lasting changes on the forest floor. Cultivation is generally associated with decreases in foliar litter mass and carbon content due to increased decomposition rates that can accompany the shift to tree species with more degradable litter (i.e., lower foliar C:N) (Compton and Boone, 2000). Working across a chronosequence of formerly farmed sites, Hooker and Compton (2003) estimated that forest-floor carbon content may take over a century to recover after land abandonment. Effects of logging are more equivocal (Yanai *et al.*, 2003), with both increases and decreases in foliar litter carbon content reported (Covington, 1981; Goodale and Aber, 2001; Latty *et al.*, 2004). There is evidence that variation in the magnitude and longevity of logging effects can be explained by differences in logging intensity, which is determined not only by the amount of biomass removed but also by the degree of mechanical disturbance (Yanai *et al.*, 2003). Likewise, logging combined with fire, which often ignited slash piles left on-site after harvests, produce more lasting changes due to increased disturbance intensity (Goodale and Aber, 2001; Latty *et al.*, 2004).

Changes in the amount and size distribution of coarse woody debris are another legacy of land use and natural disturbance. Work conducted at Harvard Forest shows that 73-year-old pine stands planted on abandoned agricultural lands have slightly higher masses and a uniform distribution of smaller size class coarse woody debris compared with

deciduous stands without an agricultural history (Currie and Nadelhoffer, 2002). Naturally reforested lands accumulate woody debris more slowly – at a rate of $0.05 \text{ mg ha}^{-1} \text{ year}^{-1}$ – and thus may require more than a century to return to pre-agricultural levels (Hooker and Compton, 2003). Similarly, intensive logging by itself or combined with fire has led to long-term decreases in coarse woody debris, especially in larger size classes, both as a direct result of tree removal and persistent changes in site quality or successional status (McCarthy and Bailey, 1994; Sturtevant *et al.*, 1997; Gough *et al.*, 2007). Fire alone removes considerably less coarse woody debris than logging and, consequently, its effects are smaller in magnitude and shorter in duration (Tinker and Knight, 2000).

Herbaceous plant communities are among the most severely impacted by past land use activity. In European and North American temperate forests, previous agriculture has led to striking changes in understory assemblages, a prominent and consistent feature of which is the reduced abundance or absence of native understory species for a century or more (Peterken and Game, 1984; Flinn and Vellend, 2005; Hermy and Verheyen, 2007). In contrast, most studies indicate that recovery from logging occurs within decades of disturbance (Halpern and Spies, 1995; Roberts and Gilliam, 2003), although long-term effects have been found (Duffy and Meier, 1992). There is also the potential for wide variation in recovery. This is illustrated by semiarid grassland plant communities cultivated half a century ago, where some old fields are compositionally similar to uncultivated grasslands and some are distinct (Coffin *et al.*, 1996). Regardless, these studies have led to important insights about the factors controlling ecosystem response to disturbance. It is clear that life-history traits play a key role in the colonization dynamics of disturbed lands (Verheyen *et al.*, 2003b). Overwhelming evidence supports the hypothesis that species mobility (i.e., dispersal capacity) determines the colonization of disturbed lands (Dzwonko and Loster, 1992; Matlack, 1994; Brunet and von Oheimb, 1998; Bossuyt *et al.*, 1999; Bellemare *et al.*, 2002; Verheyen *et al.*, 2003a). Not surprisingly, the spatial arrangement of disturbed relative to undisturbed lands is important for predicting the nature and rate of species colonization and interacts with dispersal capacity to affect community recovery via its influence on seed availability (Dzwonko and Loster, 1992; Brunet and von Oheimb, 1998; Bossuyt *et al.*, 1999; Butaye *et al.*, 2002). Working in young, secondary stands that varied in isolation from older, species-rich stands, Matlack (1994) demonstrated that diversity increases with proximity to source populations, mainly due to increased representation of poorly dispersing species. The spatial configuration of disturbed habitat relative to the source populations is also important for recovery after large, intense natural disturbances such as fire and flooding (Turner *et al.*, 1998).

Dispersal is the primary factor explaining the colonization of historically altered lands, but site conditions can also affect the distribution of herbaceous plant species by influencing plant recruitment. Indeed, variation in the establishment of species with similar dispersal abilities (Singleton *et al.*, 2001) suggests that site conditions should not be overlooked. Assembly of herbaceous plant communities on disturbed lands likely occurs as a two-stage process in which restricted seed

availability followed by a low recruitment limits colonization (Verheyen *et al.*, 2003a; Baeten *et al.*, 2009a, 2009b). Yet it remains unclear which site conditions affect recruitment. For some species, a lack of microtopographic variation or micro-site disturbance hampers establishment (Verheyen and Hermy, 2004; Flinn, 2007; Baeten *et al.*, 2009b), whereas other species appear to be influenced by edaphic characteristics (Verheyen *et al.*, 2003a). Undoubtedly, a species' life-history traits influence its requirements for establishment, which makes it challenging to identify factors that influence all species equivalently. Another complicating factor is that effects of past land use may vary with plant life stage. Several studies demonstrate that previous agriculture has neutral to positive effects on seed germination and adult plant performance (Donohue *et al.*, 2000; Singleton *et al.*, 2001; Endels *et al.*, 2004; Verheyen and Hermy, 2004; Fraterrigo *et al.*, 2006; Flinn, 2007, but see Vellend, 2005), but negative effects on seedling and juvenile survival and growth, as well as juvenile and adult survival (Endels *et al.*, 2004; Jacquemyn and Brys, 2008). The mechanisms underlying these patterns are poorly understood. One hypothesis is that due to competition from early colonizing, disturbance-adapted species reduces the ability of native species (many of which are slow-migrating perennials) to acquire resources, thereby creating bottlenecks during some stages (De Keersmaecker *et al.*, 2004). Further work is needed to evaluate the role of these and other factors.

Legacies in Soils

Land use, especially agriculture, can impose long-term changes on the physical, chemical, and biological properties of soils. A plow horizon, that is, the depth at which plowing homogenizes the soil, is one of the most apparent legacies of previous cultivation and may persist for centuries after land abandonment (Motzkin *et al.*, 1996). In addition to being visibly distinct, plow horizons are often depleted of carbon (C) and nitrogen (N) due to accelerated decomposition, reduced organic matter inputs, degradation of soil physical structure, and erosion. Labile or reactive soil C and N fractions in the plow layer can see even greater losses than total C and N pools because they are highly degradable and slower to recover (Compton and Boone, 2000). Such conditions can in turn affect soil microbial communities (Buckley and Schmidt, 2001) and contribute to changes in carbon and nutrient cycling (see legacies in ecosystem processes; Compton and Boone, 2000; Fraterrigo *et al.*, 2006a).

However, not all sites subjected to past cultivation show soil C or nutrient depletion. The specific impacts of cultivation vary with soil amendments, such as liming or fertilization, and crop management (Compton *et al.*, 1998; Knops and Tilman, 2000; Richter *et al.*, 2000). Effects on soil organic carbon, for example, depend on the amount and type of organic amendment, method of incorporation, and size and length of time of application (McLauchlan, 2006). As a result, soil C and nutrient content can increase, decrease, or show no change following agricultural land use. The stability of a chemical pool can also influence the longevity of impacts. Phosphorus, for instance, is relatively biogeochemically stable compared with C and N and often remains substantially

altered well after other chemical pools have returned to pre-cultivation levels (Honnay *et al.*, 1999; Compton and Boone, 2000; Dupouey *et al.*, 2002; Grossmann and Mladenoff, 2008).

Relative to agriculture, logging and natural disturbance have a more limited impact on soils. Mineral soil C and N content of sites logged approximately 100 years ago is comparable with that of old-growth forests, although logging and fire together can slightly reduce soil C and N (Goodale and Aber, 2001; Latty *et al.*, 2004; Gough *et al.*, 2007). Regional studies of disturbance impacts on soil C and nutrient content suggest that the long-term effects are greatest following agriculture, followed by logging and fire (Grossmann and Mladenoff, 2008).

Despite slow rates of accumulation, depleted soil C and N pools recover eventually in most ecosystems (Knops and Tilman, 2000; Hooker and Compton, 2003; Matlack, 2009). The factors that influence C and N recovery operate via their effects on soil development and C and nutrient inputs and include vegetation recovery, climate, and soil texture and mineralogy (Burke *et al.*, 1995; Ithori *et al.*, 1995; Knops and Tilman, 2000; Post and Kwon, 2000; Springob *et al.*, 2001; McLauchlan, 2006). Because these factors differ across sites, rates of recovery vary widely within and among the ecosystems (McLauchlan, 2006). Empirical and modeling work indicate that active soil organic matter in once-cultivated grasslands returns to precultivation levels within 30–50 years, whereas total soil C may take 100–150 years to recover (Burke *et al.*, 1995; Baer *et al.*, 2002; McLauchlan *et al.*, 2006). Similarly, accrual rates of soil C in formerly cultivated temperate forests range from 1.5 to 5.8 g C m⁻² year⁻¹, which suggests at least a 100-year recovery period (Hooker and Compton, 2003; Paul *et al.*, 2003). Climate and soil texture may ultimately constrain ecosystem C accrual by regulating biomass production, but more work is needed to evaluate how this relates to soil C accumulation (Johnson *et al.*, 2000; Johnson and Curtis, 2001).

Ecosystem Process Legacies

Persistent changes in soil properties can result in altered ecosystem processes. Globally, primary production is controlled by climate and soil texture (Johnson *et al.*, 2000), but within regions, previous land use can influence site quality, thereby reducing the rates of growth and biomass accumulation. These effects are most severe under repeated disturbance or when the duration of previous land use is long. For example, forest stands in the Great Lakes region that were disturbed twice by harvest and fire stored on an average 45% less C annually than those receiving the same disturbance only once due to reduced site quality (Gough *et al.*, 2007). Similarly, pine stands in southeastern USA that were previously farmed for cotton and other crops show acute N deficiency and reduced growth, despite fertilization during cropping and 50–125 years of forest development (Richter *et al.*, 2000).

Previous land use can also result in changes in N cycling and retention. Northern hardwood forests logged and burned 80–110 years ago have lower nitrification rates and export less nitrate to adjacent streams compared with old-growth forests

due to an increase in the strength of the biomass N sink (Goodale *et al.*, 2000; Goodale and Aber, 2001). By contrast, cultivation is associated with increased nitrification rates. The reasons for this are unclear, but one hypothesis is that increased nitrification is related to soil organic matter depletion. As soil microbes become substrate-limited, they may increase the rate at which they degrade soil organic matter and nitrify more N in the process (Compton and Boone, 2002).

Implications

Given the strong influence of historical events on ecosystem structure and function, it is clear that understanding the land use and disturbance legacies is fundamentally important for managing and restoring ecosystems. In many cases, ecosystem responses to current landscape-change drivers cannot be interpreted without knowing the historical context. For example, experimental and observational studies indicate that the N saturation status of forests cannot be accurately predicted without knowing the forest history (Aber *et al.*, 1998; McLauchlan *et al.*, 2007). Rates of C accrued and sequestered in biomass also depend on land-use history, making it an important factor in explaining global C dynamics (Caspersen *et al.*, 2000). Past events can influence the success of ecosystem restoration activities by altering the pool of species available for reintroduction. One result might be that the restoration activities such as prescribed burning have little effect on the patterns imposed by past land use (Motzkin *et al.*, 1996). The composition of disturbed and undisturbed communities may also be so different as to respond to management activities in unique ways (Brudvig and Damschen, 2011). More work is needed to develop strategies for managing landscapes with diverse histories.

Conclusions

Land use and disturbance legacies can be detected in plant communities, soils, and ecosystem processes, resulting in altered ecosystem structure, composition, and function. Recognizing historical legacies aides in interpreting contemporary ecosystem patterns and responses to modern landscape-change drivers. For these reasons, landscape legacies should be viewed as an integral component of ecological science and landscape management.

Glossary

Disturbance A relatively discrete event that results in mortality of plants or animals or an event that is uncharacteristically intense or long-lasting. Wildfire, tornados, and logging are disturbances that are generally stochastic in location and time. Floods or extended dry periods (droughts) are considered disturbances if they are unusually large or intense.

Endogenous process Process that emerges from biotic and abiotic interactions internal to the system of interest. Examples include vegetation growth and succession, dispersal of organisms within a landscape, and topographic influences on microclimate. Some human activities may be considered endogenous – for example, various crop rotation systems – if they are well established and responsive to local needs.

Exogenous process Process external to the system of interest. For landscapes, exogenous processes would include climate change or species migration into the landscape. Human activities may be considered exogenous if they are novel, permanent (e.g., housing development), or driven by external forces (e.g., the world market for timber).

Geographic information system (GIS) Computational system for storing, managing, manipulating, and displaying spatial data. Because landscape models are inherently spatial, strong links to GIS are either built into such models or are required to interface with the model input and output data. Many GIS, both free and commercial, are available for use with landscape models.

Resolution The resolution of information represented within a landscape model has three primary components:

spatial, temporal, and taxonomic. *Spatial resolution* refers to the smallest unit size or area represented (synonymous with *grain*). For vector data, resolution is the minimum mapping unit. For raster data, it is the cell size. *Temporal resolution* refers to the frequency at which various social or ecological processes operate. Common examples include hourly, daily, monthly, and annually. *Taxonomic resolution* is the degree of aggregation of species information. The smallest unit possible is species-specific information. *Taxonomic* aggregations typically used in landscape modeling include species, functional groups, potential vegetation types, and successional states.

Scenario A discrete suite of assumptions regarding future drivers of landscape change that are fed into a landscape model or models. The list of assumptions often includes future climate, future disturbance regimes, and future management or land-use policies. Multiple scenarios can be created to form a full factorial matrix that highlights experimentation and statistical rigor. Alternatively, fewer scenarios can be assembled into central “story lines” that highlight key management or policy options.

Stochastic process Process in which one or more simulated events or rates has values that are derived in part from a probability distribution function (e.g., Gaussian, Weibull, exponential). Therefore, such events or rates are not typically “random” (although random is a valid probability distribution function) but are unpredictable. Examples of simulated stochastic processes include the location of lightning strikes, daily maximum temperature, and wind speeds.

Introduction

A sufficient understanding of the threats to biodiversity and the opportunities to preserve or enhance biodiversity requires an acknowledgment of the broader context within which the various components of biodiversity operate. Over the past several decades, managers have realized that consideration of only small watersheds or forest stands is not sufficient to maintain biodiversity (Hansson and Angelstam, 1991; White *et al.*, 1997; Foley *et al.*, 2005; Fischer and Lindenmayer, 2007; Lindenmayer *et al.*, 2008). Insufficient attention to the broader context within which an area of interest (e.g., a national park or wilderness area) resides can lead to population decline, local extirpation, or catastrophic disruption due to large, infrequent disturbance events (den Boer, 1981; Tilman *et al.*, 1994; Huxel and Hastings, 1999; Brashares, 2010; Spencer *et al.*, 2011). This broader context can be considered the *functional landscape*: an area large enough to capture all of those processes that maintain or reduce biodiversity and large

enough to provide sufficient habitat for populations of native species. A functional landscape is typically smaller than a biome but larger than a first-order watershed and several times larger than the maximum disturbance size (Baker, 1989a; Dunning *et al.*, 1992; Turner *et al.*, 1993, 1995; Forman, 1995).

Functional landscapes (*landscapes* henceforth) are an intuitive unit for studying and managing biodiversity. By encompassing most of the processes influencing biodiversity, landscapes afford the opportunity to practice inclusionary management that is more holistic and considerate of all relevant processes and elements (the individual components of a landscape – for example, forest patches, stream corridors, and grass or shrub fields). However, landscapes pose distinct challenges for ecologists and managers. Because of their size, they are inherently nonreplicable (Hurlbert, 1984). Also because of size, significant change at the landscape scale typically occurs over many decades: changes to composition, structure, or function emerge more slowly when averaged across large

numbers of each landscape element. Such long durations are generally not commensurate with the available funding for either research or management. For management, these concerns are particularly acute because trends occurring at a landscape scale are often difficult and expensive to reverse through restoration efforts. Borrowing a business aphorism, changing course at the landscape scale is akin to turning an oil tanker around: it happens slowly at best. And no one wants to be held accountable for running an ecosystem into the shoals of lost biodiversity or reduced ecosystem functioning.

Because of these spatial and temporal challenges, both scientists and managers increasingly rely on landscape models to understand and predict change at these spatial and temporal scales. A landscape model is a mathematical and logical representation of a functional landscape that includes the subset of exogenous and endogenous processes expected to explain a majority of the coarse-scale spatial and temporal variability. These processes nearly always include disturbances and vegetative succession. A typical landscape model will include a representation of vegetative change (the author will discuss techniques in the following sections) and one or more stochastic disturbances: wildfire, development and urban expansion, forest management, windthrow, and so on. As with all models, an empirical foundation is necessary to derive the mathematical and logical abstractions of the real system.

Landscape models differ from other kinds of ecological model because they are spatially explicit, depicting the composition, arrangement, and geographic location of the various landscape elements. In practice, this means that the models are often closely linked to a geographic information system (GIS) for managing the spatial information. Results are often provided via maps of biodiversity or other conditions of interest, allowing an intuitive assessment of spatial variation. Maps are particularly valuable for communicating with stakeholders. Unfortunately, accompanying maps of uncertainty are seldom provided.

Landscape models also depict the spatial interactions among constituent elements. Spatial interactions are the lateral transfer of information, matter, or energy generated by ecological processes (Reiners and Driese, 2001). Movement of matter and energy includes the lateral transport of water and dissolved nutrients. The transfer of matter and energy may also be generated through disturbances. Wildfire is an archetypal spatial process because it releases and transfers energy and the size and duration of wildfire is highly dependent on the spatial configuration of fuels and topography (Hargrove *et al.*, 2000; Finney *et al.*, 2007; Schmidt *et al.*, 2008).

The lateral transfer of information is synonymous with species distributions and community composition and is transferred across the landscape through dispersal and migration. Similar to wildfire, dispersal is often highly dependent on landscape configuration and fragmentation (Miller *et al.*, 1997; King and With, 2002; Higgins *et al.*, 2003b; Iverson *et al.*, 2004; Scheller and Mladenoff, 2008). Without spatial interactions – or if spatial interactions are weak – landscape models can be reduced to a collection of individual units (e.g., stands), and these units could simply be multiplied by the area within the landscape that they represent. Further explication of when a spatially dynamic model (one that includes spatial interactions) is necessary is provided below (see Landscape Modeling Approaches).

By representing the dominant processes at a scale relevant to understanding and managing biodiversity and by representing the spatial configuration and interactions of a landscape, landscape models allow empirically derived knowledge to be extrapolated to larger spatial and temporal domains. Doing so, we can begin to engage in meaningful *ecological forecasting* (Clark *et al.*, 2001), providing managers and policy makers tools for enhanced decision making that incorporates knowledge about the future, however limited (Pielke, 2003).

Landscape models are frequently paired with scenarios that can be relatively simple narratives about future policies or conditions – for example, the *Millennium Ecosystem Assessment* (2005). Scenarios can also be framed within an experimental design with multiple factors along two or more gradients (e.g., three levels of fire rotation period $\times$ three levels of harvesting in a full factorial design). Each individual scenario is then used to project how a landscape will change given the associated suite of assumptions about the frequency and intensity of the constituent processes (particularly of anthropogenic origin) (Carpenter, 2000). Typically, the results from each scenario are then compared with each other and with empirical data when available (see Conclusions). By comparing results among scenarios, the need for absolute accuracy is reduced as the *relative* merits of different policies or assumptions can still be assessed.

Although serving the utilitarian purpose of extrapolating knowledge to larger spatial and temporal domains, landscape models also enable a synthesis that is otherwise impossible. As knowledge about biodiversity expands and the threats to biodiversity multiply, the requisite number of processes that must be integrated and managed to preserve biodiversity grows exponentially. However, the human capacity to synthesize the effects of many processes, each operating at unique and often disparate scales, is limited. Landscape models allow many different processes to operate within and interact across a landscape. Patterns will emerge (*emergent behaviors*) that could not be anticipated using studies of isolated processes or intuition alone. For example, simulations of climate change in Siberia that included wildfire, logging, and insect mortality revealed that the expansion of harvesting in combination with increased insect activity will potentially have a far greater effect on forest composition than the direct effects of climate change alone (Gustafson *et al.*, 2010).

Because landscape models often incorporate multiple stochastic processes, they are also well suited for partitioning the total uncertainty of a landscape projection into its components: parameter, model, and inherent uncertainty (Haag and Kaupenjohann, 2001; Higgins *et al.*, 2003a; Millar *et al.*, 2007). Parameter and model uncertainty are artifacts of the modeling process and represent the current limits of knowledge about the system. Inherent uncertainty is the accumulated effect of all nondeterministic variation. For example, seed dispersal has significant inherent uncertainty as we can never know exactly how far an individual seed may travel. The exact time and location of lightning ignition of fires is similarly unknowable. Inherent uncertainty may seem to deflate ambitions for ever-increasing model accuracy. However, even if the accuracy of a given model projection is weak or unknown (as is the case for all projections of the deeper future), knowledge about the sources of uncertainty

(e.g., Allen *et al.*, 2000; Xu *et al.*, 2009) can be extremely valuable to managers. If a system has relatively low inherent uncertainty, then human agency will be relatively more effective. If the opposite is true, then caution is warranted before investing considerable resources into attempts at guiding or dictating landscape change.

Finally, landscape models also provide a critical heuristic function. The process of formulating, parameterizing, calibrating, and validating a landscape model requires the synthesis of multiple sources of data and models. A landscape model typically requires vast quantities of data that are processed in advance of conducting any simulations. For example, even the simplest landscape model requires remotely sensed data that are classified to a spatial and taxonomic resolution that are congruent with the questions at hand. More detailed or complex landscape models may require additional edaphic or topographic data or more detailed taxonomic data. In addition, formulating how the various processes will interact across space and time requires a deep understanding of the ecology of the system (and therefore modeling efforts often involve teams of scientists). Existing representations of processes may need to be altered or discarded if they were developed for a scale substantially different from the other model components. Validation requires more data still and is difficult to obtain for long-term or projected models. In total, the modeling process is dominated by data synthesis and analysis with a relatively small amount of time devoted to actual simulations.

Landscape Modeling Approaches

When is a landscape model useful or necessary? Landscape models are useful when the representation of exogenous and endogenous processes, represented within a geographic framework, and with spatial interaction among landscape elements is required to project, understand, and manage landscapes for biodiversity. These are also the criteria the author used to select modeling approaches for review. There is an incredible diversity of landscape models – more than can be summarized here. These models span broad gradients of complexity, specificity, usability, and application. Many excellent reviews have been written summarizing the past and current state of landscape models (Baker, 1989b; Mladenoff and Baker, 1999; Keane *et al.*, 2004; Scheller and Mladenoff, 2007; Seidl *et al.*, 2011). More information about the mechanics of developing landscape models is also widely available (Maxwell and Costanza, 1997; Scheller *et al.*, 2010). Rather than an exhaustive and complete list, the author focussed on four of the most common approaches to formulating (or applying) landscape models: state-and-transition models, process models, hybrid models and multimodeling, and neutral models (an approach to applying models, rather than a type). The author will highlight their respective strengths and limitations and the appropriate domain of application for each.

Ideally, a model is no more complex than necessary to answer the given question. Given the enormous additional complexity introduced by the inclusion of spatial interactions (Shugart Jr., 1998; Strayer *et al.*, 2003), it is critical to decide when the representation of spatial processes – and therefore

the need for a landscape model at all – is justified. All ecosystems contain spatial interactions. The question is whether the policy, management, or ecological question can be answered with a simpler nonspatial model or whether the additional complexity is required. There are no absolute answers; however, general criteria can be outlined based on the strength of spatial interactions at the chosen model resolution and extent (Strayer *et al.*, 2003). If a spatial process is occurring at a resolution much finer than model resolution, then the process is often considered “noise” that can be safely averaged without loss of important information. For example, when modeling the effects of climate change on terrestrial systems at regional or continental systems (e.g., Bachelet *et al.*, 2003), the inclusion of the effects of competition among neighboring trees or fine-scale propagules dispersal would be unlikely to reduce uncertainty at the intended scale. Inclusion of the effects of tree species migration via dispersal may, however, be required if substantial range shifts are expected over the simulated duration. Similarly, if a spatial process naturally occurs across extents far greater than the focal extent, the process can be represented as a simple rate (potentially changing through time). For regional landscapes (or smaller), climate is often treated in this fashion even though we recognize that weather is a very spatially dynamic process.

All models are compromises. The data available to parameterize and validate models are limited, as are the resources (fiscal, temporal, and computational) available for developing and applying a model. Is it important that the model be able to run on a typical desktop computer? Is an intuitive user interface necessary for the intended user to be able to quickly implement the model? Each model developer must rank the priorities for resolving the question at hand.

Models must also compromise among processes for the allocation of complexity. For example, a landscape model with a fire component that represents hourly growth of a fire and flame lengths at a 1-m resolution necessarily devotes fewer resources to landscape processes that unfold over many decades (e.g., tree species migration). If the model developer devoted most resources to developing a model of individual trees, then the biogeochemical components may be simplified or lacking altogether. Each of the four types (Table 1) described in the following sections represent the compromises and such sacrifices. None of these model types is appropriate for all situations and questions.

State-and-Transition Models

State-and-transition models are typically used to address management questions for which distinct vegetative conditions or classes are readily identifiable and their relative abundance is an important consideration. For example, Pastor *et al.* (2005) modeled forest change in northern Minnesota as a function of harvesting using an age-dependent state-and-transition model. They concluded that a narrow range of harvest ages will reduce the amount of the landscape in a regeneration state, a result that is counter to emerging trends toward managing with a broader range of harvest ages.

State-and-transition models place each landscape element into one of a limited number of states (Cattalino *et al.*, 1979;

Table 1 Four general landscape modeling approaches, example questions, and strengths and weaknesses

Model approach	Example question	Strengths	Weaknesses
State-and-transition	How will the relative abundance of discrete vegetation classes change through time?	Relatively straightforward logic; easier to parameterize; simplification facilitates collaboration; reduced computational requirements.	Less flexible responses to novel climates, introduced species, altered disturbance regimes; nonstationary landscape dynamics poorly represented.
Process	How will net biome production change if wildfire increases with climate change?	Highly flexible; ability to represent nonstationary landscape dynamics; can represent changing ecosystem process rates.	Steep parameterization requirements; requires specialized knowledge and therefore is less suitable for stakeholder engagement; high computational requirements.
Neutral	Are patch size or shape important determinants of population migration?	Assess strength of individual processes; location neutral and not context dependent; testing of multiple landscape configurations.	The results are more abstract; artificiality may render results less applicable to actual threats to biodiversity; lack of place-based output maps reduces stakeholder engagement.
Hybrid or multimodeling	Do landscape-scale fire dynamics influence carnivore population viability?	Integration of multiple domains (e.g., forests and animal metapopulations); integration across broader range of spatial and temporal scales; increased ability to assess sources of uncertainty.	High complexity can overwhelm modeler's ability to partition sources of variation; need to validate across multiple domains; communicating system behavior to nontechnical audiences is challenging.

**Figure 1** Conceptual diagram of a mid-Atlantic pine barrens state-and-transition model.

Klenner *et al.*, 2000; Acevedo *et al.*, 2001; Monticino *et al.*, 2002; Pastor *et al.*, 2005). These states typically represent the vegetative condition at a given time. For example, in the eastern US, a landscape element could be initially classified as even-aged pitch pine if satellite and field data indicate that the unit is dominated by *Pinus rigida* with an average age between 30 and 100 years (Figure 1). The transition to a different predetermined alternative state may occur if either a set amount of time has passed (succession) or a transition is triggered by a disturbance event. The even-aged pitch pine may transition to oak-pine mix 70 years after initiation unless a fire is simulated, changing it to early seral pitch pine or uneven-aged pitch pine, depending on fire severity (Figure 1).

Transitions among states may be dictated by disturbance as previously noted or may be determined via a transition probability matrix (Logofet and Lesnaya, 2000; Yemshanov and Perera, 2002). In this case, a state may transition to one of many possible alternate states based on a probability assigned to each transition. The combination of a fixed state and a transition determined in part by a stochastic process is considered a *semi-Markov* model.

The number of states and their taxonomic resolution (e.g., three classes of pitch pine vs. forest, prairie, and savannah), and the number of transitions is dependent on the objectives of the research or the management application. Shorter duration (<50 years) simulations often stratify a landscape into potential vegetation types with a suite of states for each type, whereas longer duration simulations may focus more on transitions among major land types (e.g., agriculture, forest, pasture, developed).

Because of the finite number of states (and therefore transitions), state-and-transition landscape models are conducive to rapid deployment and collaborative model construction. One of the most commonly used state-and-transition models, the Vegetation Dynamics Development Tool (VDDT), has an intuitive graphic interface that allows groups of scientists and managers to quickly visualize a model and focus their efforts on deliberately constructing the states and transitions that best represent the dynamics of their system (Hemstrom *et al.*, 2001; Shifley *et al.*, 2008). The relative simplicity also maximizes transparency and generates greater “buy-in” from local managers and stakeholders. This process of constructing state-and-transition models to engage a broader group of participants has been widely used by the Nature Conservancy in North America (Shlisky *et al.*, 2005).

However, the finite states also limit the inferential power of these landscape models. Most landscapes around the world today are in part dominated by one or more *nonstationary* processes, meaning that their frequency or magnitude is changing through time. Consequently, many states may cease to be significant components of their respective landscapes or the transitions among states may be substantially altered through time. Novel communities (states) may emerge due to climate change (Williams *et al.*, 2007) or invasive plant species. Invasive (or climatically released) insects may become the dominant process driving vegetative change (Ward and Masters, 2007; Kurz *et al.*, 2008).

Process Models

All landscape models represent one or more processes, and therefore this landscape model type is a misnomer. What distinguishes these models is that all processes, including succession, are explicitly represented and there are no fixed states or transitions. Rather, plant community composition is an emergent property itself. Depending on how succession is represented and on the taxonomic resolution, plant community composition may be a function of disturbance intensity and type, plant competition for light or nutrients, seed dispersal, and other species vital attributes (Mladenoff *et al.*, 1996; Roberts, 1996). Because composition is more nearly continuous, all other processes can be formulated to be more sensitive to the effects of plant community composition and diversity. In particular, ecosystem processes (e.g., aboveground net primary productivity, soil respiration) can more readily be incorporated as these generally require a tight coupling between vegetative composition, structure, climate and soils (Scheller *et al.*, 2011a).

Such landscape process models therefore have much greater flexibility to deal with nonstationary processes, notably climate change. Novel communities can emerge from the interplay between stochastic disturbance processes (themselves responding to climate), species vital attributes, and ecosystem processes that will dictate other physiological constraints (e.g., nitrogen availability, soil moisture, Scheller *et al.*, 2011a) (Figure 2). Such an approach is essential for projecting landscape capacity to sequester carbon and provide habitat further into the future (> 50 years).

The added flexibility does, however, come at a substantial cost. The data required to parameterize such models is orders of magnitude greater than for state-and-transition models. And the process of constructing and parameterizing these landscape models is at best a specialized skill and at worst hopelessly opaque to anyone outside of the discipline. Policy makers, managers, and stakeholders can feel removed from the modeling process and are generally unable to assess the quality of the research. The important drivers that may emerge – N availability, litter lignin content – are not readily measurable by land managers and often only loosely related back to the task of managing for biodiversity.

Hybrid and Multimodeling

An emerging trend is the combination of one or more modeling approaches to understand and project changing

Figure 2 Conceptual diagram of a process landscape model, emphasizing ecosystem processes and spatially dependent disturbances.

biodiversity. In particular, hybrid models and multimodeling offer the opportunity to include processes or interactions across a broader range of spatial, temporal, or taxonomic resolutions than might be possible with a single modeling approach.

To better understand vegetation change, hybrid models have been deployed to represent finer-scale processes using a different modeling paradigm than is used to represent broader landscape process interactions. For example, competition among individual trees and subsequent growth may be simulated using an individual tree model (Robinson and Ek, 2003; Seidl *et al.*, in press) or a gap model (Pastor and Post, 1988; Seidl *et al.*, 2005). These fine-scale models can be stitched together spatially to form a continuous landscape (e.g., Urban *et al.*, 1991; Bragg *et al.*, 2004). Alternatively, individual tree data can be averaged using ecological field theory and scaled up to allow for the efficient calculation of processes that operate at larger spatial or temporal scales (e.g., Seidl *et al.* in press). The advantage of hybrid forest models is the inclusion of individual trees, their growth, and competition with neighbors. The challenge is the additional parameterization and data required. To date, these data are seldom captured by the remote sensing tools available, and hybrid models have been limited to relative small landscapes (< 10,000 ha).

Multimodeling (or *model coupling*) has also been extended to assessing animal populations. The challenges of overlaying stochastic animal populations on top of the existing stochastic disturbance dynamics are considerable. However, advances in software and computer power have accelerated the ability to consider both changing habitats and changing populations simultaneously (Larson *et al.*, 2004; Akcakaya *et al.*, 2005; Shifley *et al.*, 2008). For example, to project changes in the population of fisher (*Martes pennanti*) in the southern Sierra Nevada, California, USA, a landscape change model was coupled with a metapopulation model (Spencer *et al.*, 2011; Syphard *et al.*, 2011). As a result, two of the largest sources of uncertainty were incorporated: wildfire and fisher dispersal.

By doing so, a more accurate estimate of inherent uncertainty was achieved (Scheller *et al.*, 2011b).

Neutral Models

Neutral models are not a model type in and of themselves but rather a unique application of landscape models (Gardner *et al.*, 1987; With and King, 1997). Neutral modeling is the process of applying a landscape model to a strictly hypothetical landscape. In this case, the complexity inherent in parameterizing an actual landscape is jettisoned in favor of a focus on the processes themselves. A neutral modeling approach allows for much more precise testing of model sensitivity to landscape configuration and community composition than is possible on a real landscape. The goal of neutral landscape modeling is a more fundamental understanding of the processes that control landscape change across *all* landscapes rather than the narrower domain of a real landscape. Real landscapes simply never contain the full range of possible landscape configurations and species that may inform longer-range management efforts. As an example, Huxel and Hastings (1999) used neutral models to examine how the placement of restoration efforts (adjacent to existing habitat vs. random placement) could significantly influence habitat restoration success. Attempting to find a suitable suite of similar landscapes (with replication) for such experimentation would have been impossible.

Although further removed from the immediacies of landscape management, neutral models can potentially inform managers about potential solutions or enhancements that are not immediately apparent from an examination of current conditions (Huxel and Hastings, 1999; With *et al.*, 1999; King and With, 2002). The risk is further detachment from management relevancy: maps of actual landscapes and geographically grounded projections of landscape change remain extremely powerful tools for communicating the science of landscape change.

Conclusions

The limitations to landscape models are similar to that of all models, with one important caveat. All models are limited (or strengthened) by the empirical foundation on which they are built: by the data underlying their formulation, the data available to parameterize a model in a novel setting, the computational limits to complex simulations, and the software limitations to managing complex algorithms and architectures. With limited experience, I assume these limitations also apply to models of beating hearts and hurricane trajectories.

However, landscape models, like climate change models, are additionally limited by the ability to validate results. When projecting more than a few years into the future, validation of model results – the cross-check against reality that has made weather forecasting so successful – requires the continual collection of spatially explicit data through time (Rastetter, 1996; Rykiel, 1996; Haag and Kaupenjohann, 2001; Gardner and Urban, 2003). If projecting more than 10 or 20 years,

validation would require patience and funding not typically afforded the average scientist or manager. In addition, it is important to remember that because of stochastic events, the actual observed landscape is but one of many possible outcomes that could have occurred. Rarely will a single model simulation match reality. Thus, even assuming that spatial data are collected, validation should be against confidence intervals generated by running the model many times (e.g., model replication).

Complete validation may be the gold standard of modeling (as double-blind experiments are to medicine), but it is only one route to building confidence in the knowledge gained from models. Other avenues for building confidence in landscape model results include the validation of individual processes, model documentation, model transparency (e.g., closed vs. open source), and repeated application across diverse systems. Deploying a rigorous software engineering process during the development stage can maximize model verification (*sensu*; Aber, 1997) and has become more important as model complexity has increased (Scheller *et al.*, 2010).

It is incumbent on those who build and apply landscape models to follow a few general principles. First, quantify model sensitivity. There is little value obtaining precise leaf nitrogen estimates if wildfire explains 90% of the variation in species composition. Conversely, if leaf nitrogen is the controlling variable, more effort can be placed on obtaining empirical estimates.

Second, the inability to validate the complete landscape does not preclude the validation of individual processes. Often available knowledge about individual processes (tree growth rates, wildfire spread, logging patterns) is large and should be rigorously utilized.

Third, replication is essential. The existence of inherent uncertainty in reality and the incorporation of stochastic processes into models ensures that no single model simulation will be broadly representative of the future.

Fourth, communicate uncertainty. Although maps of projected landscape change are powerful tools for communication, it is essential that the underlying uncertainty be expressed through time series with replicate standard errors, probability surface maps, or similar approaches.

Similarly, it is incumbent on the managers and policy makers to be aware of these principles and to recognize those model applications that do or do not adhere to them. Unfortunately, many managers and policy makers instinctively distrust model results and do not engage in the process. This is perhaps in part due to inadequate education and outreach on the part of those who conduct modeling research (Pielke, 2003). It is also true that model results have often been presented as *predictions*, which imply a high level of accuracy, and the degree of uncertainty has been underrepresented. Modelers need to articulate what managers can learn from models while acknowledging that we live in a “black swan” world (Taleb, 2007).

As the collective challenge to preserve biodiversity increases, tools that enable learning about the future are increasingly valuable. Landscape models – in conjunction with well-formulated scenarios – offer a route to understanding and managing biodiversity across large areas and long

durations. The relentless increase in spatial data (particularly from remote sensing), computing power, and the sophistication of landscape models has enabled scientists and managers to look further into the future and with greater accuracy than ever before. Continued success and improvement is possible, dependent on the ability of scientists to provide a transparent, collaborative, and rigorous system that maximizes learning while acknowledging uncertainty.

Latitudinal and Elevational Range Shifts under Contemporary Climate Change

Jonathan Lenoir and Jens-Christian Svenning, Aarhus University, Aarhus, Denmark

© 2013 Elsevier Inc. All rights reserved.

Glossary

Front edge Stable margin of a species' range where population size is growing.

Leading edge Dynamic margin of a species' range where it is expanding into neighboring unoccupied areas.

Range core Central part of the distribution of a species.

Range periphery Marginal parts of the distribution of a species.

Rear edge Stable margin of a species' range where population size is declining.

Species' niche The scope of environmental conditions under which a species is able to maintain stable or increasing populations.

Species' optimum The value of a given environmental variable at which a species reaches its maximum probability of occurrence or abundance.

Species' range The spatial distribution of a species, that is, the sum of all geographic locations of its individuals over a given period in time.

Species' response curve The relationship between a species' probability of occurrence or its density (number of individuals per unit area) and the values of a given environmental variable.

Trailing edge Dynamic margin of a species' range where it is becoming locally extinct, causing the range to retract.

The concept of range shifts refers to the dynamic process whereby species shift their distribution over time, tracking geographic shifts in the climate and habitat conditions that they require. Range shifts are also commonly defined as migration events that occur on decadal to millennial or longer time scales, usually beyond the life span of individuals. In contrast, the concept does not include migration events occurring over the life span of individuals, that is, on a seasonal to annual or shorter time scales, as a result of recurring movements of individuals between spatially separate habitats in order to avoid temporarily unfavorable conditions. It also does not include essentially stochastic long-distance dispersal events of a single or few individuals that fail to establish new populations. Recently, species range shifts have attracted a great deal of interest from the scientific community as a direct consequence of the increasing focus on current global environmental changes, notably the changing climate (IPCC, 2007a). There is now a growing body of studies reporting and forecasting species range shifts across the main geographic dimensions (latitude, longitude, and elevation) as a response to both contemporary and future changes in climatic conditions. Here, the focus is on realized range shifts in response to contemporary climate change, a phenomenon that is of key importance for developing well-founded predictive models of range shifts under expected substantial future climate change (IPCC, 2007b). Because dramatic range shifts have also occurred in the geological past, species range shifts, until recently, have been described in textbooks through paleontological examples, but contemporary range shifts are now becoming even more evident.

Species' Range: Geographic Dimensions and Ecological Drivers

As a species' range can be defined by the geographic locations of all its individuals over a given period of time (Brown and

Lomolino, 1998), it is often difficult and challenging to capture and represent it. Several abstractions of the real distribution of a single species have been used, with the most frequent approaches being to represent a species' range as outline, dot, or contour maps in a two-dimensional geographic space, most often across the latitudinal and longitudinal dimensions. One could also represent a species' range in a three-dimensional geographic space by adding occurrence along elevational gradients to the representation (Figure 1). Another more simplistic abstraction is to project the known or estimated occurrences of the species against one of these three dimensions. Hence, latitude, longitude, and elevation constitute the geographic dimensions over which a species' range is estimated, and a species' range shift is defined as changes in these geographic dimensions over the fourth dimension: time (Figure 1).

A species' range is generally understood to be at least partly determined by the species' environmental requirements and tolerances, that is, its ecological niche (Hutchinson, 1957; Soberon and Nakamura, 2009). The ecological niche is typically considered a multidimensional space (or "hypervolume"), in which the different dimensions represent different environmental conditions (Hutchinson, 1957). Especially at large scales, climate is often thought to constitute the niche axes that are most relevant for species ranges (Pearson and Dawson, 2003). Therefore, one should be able to deduce a species' climatic niche from its range. Unfortunately, the geographic distribution of a species is unlikely to fully represent its ecological niche for at least three reasons (Colwell and Rangel, 2009): (1) geographic unavailability of some portions of its ecological niche; (2) geographic inaccessibility due to its limited dispersal abilities (Svenning and Skov, 2004; Blach-Overgaard *et al.*, 2010); and (3) geographic control by constraining species interactions (Case *et al.*, 2005). Throughout this article, therefore, the species' range is solely being considered as an incomplete geographic reflection of the species' niche. Still, it is useful to relate ranges to the niche concept in

Figure 1 Representation of a species' range (red dots) across the three geographic dimensions (latitude, longitude, and elevation) of a given landscape in the Northern Hemisphere (the "volcano" data set available in R has been used (R Development Core Team, 2010) for illustrative purpose) and at two different time periods: t_1 (a) and t_2 (b). Note that the illustrative species shifted its geographic range upward and poleward between t_1 and t_2 .

order to understand the mechanics of range shifts under climate change. Given this conceptual framework, a given species may respond differently to the environmental changes over time. It may (1) relocate toward newly suitable geographic locations, completely or partially tracking its environmental requirements (range shift) (Lenoir *et al.*, 2008); (2) remain within the same locations and acclimate or adapt to its new environment (niche shift) (Davis and Shaw, 2001); (3) go extinct (Svenning, 2003); or some combination of these responses. In short: move, adapt, or die (Maggini *et al.*, 2011).

How Do Species Shift Their Ranges?

Species' ranges are not static over time, but constantly shift either more or less stochastically by means of population dynamics within a steady-state environment or directionally through population dynamics within a shifting environment that is spatially autocorrelated (Figure 2). Although many human-induced changes in the global environment, such as land-use change, climate change, nitrogen deposition, biological invasions, and atmospheric CO₂ increase (Sala *et al.*, 2000) may trigger species range shifts, here the focus is on the effect of contemporary climate change.

The Mechanics of Range Shifts: Distinction between Range Core and Range Periphery

In a steady-state environment, stochastic range shifts are the net result of growth, decline, colonization, and extinction processes that are tuned to different temporal scales (Breshears *et al.*, 2008). Whereas local populations grow and decline over relatively short time periods, local populations colonize and go extinct over much longer time periods, especially for long-lived species. Additionally, growth, decline, colonization, and extinction processes are tuned differently across a species' range (Figure 2(a)). Notably, there may be a strong core-periphery distinction leading to lower population densities near the peripheral area in comparison to the core area (Brown and Lomolino, 1998). Here the term "core" instead of "center" is explicitly used when referring to the geographic location of the abundance peak within a species' range. Indeed, the geographic location of the highest population density or abundance of a given species within its range is not necessarily located at the geometric center or centroid of its range (Murphy *et al.*, 2006), even though the core area of a species' range may be represented at the range center for simplicity (Figure 2(a)). At the core area of a species' range, sometimes called species' optimum to avoid confusion with the geometric center, local populations are generally thought to experience favorable conditions leading to enhanced fitness and population density. In other words, at the core, birth and emigration rates may exceed death and immigration rates, respectively, leading to sink populations (Pulliam, 2000). Such populations not only are likely to grow within the suitable localities already occupied, but are also likely to colonize and establish populations in suitable localities not previously occupied by the species in the core area of its range and even beyond, if dispersal and biotic interactions are not constraints. Decline and extinction processes might occur there as well, but to a lesser extent, unless there is a drastic shift in environmental conditions. At the peripheral area of a species' range, local populations may experience unfavorable conditions, leading to reduced fitness and reduced population density. In other words, at the periphery, death and immigration rates may exceed birth and emigration rates, respectively, leading to sink populations (Pulliam, 2000). Such range-edge sink populations will tend to decline and eventually go extinct, except when maintained by a "rescue effect" through constant immigration from source populations, typically located close to the core area of the species range. Growth and colonization processes might occur there as well, but to a lesser extent, unless there is a drastic shift in environmental conditions.

Directional Range Shifts under Climate Change

Let us now consider shifting conditions in the environment, such as the temperature and precipitation changes observed during contemporary climate change (IPCC, 2007b). Any shift in climatic conditions in a given location will impact the individuals living there and thus affect population dynamics locally. For instance, species sensitive to temperature may respond to a warmer climate through local changes in growth, decline, colonization, and extinction rates. On the one hand,

locations within the peripheral area of a species' range that were too cold and therefore less suitable might become more suitable in a warmer climate, thus turning sink populations into source populations with higher growth and colonization rates. On the other hand, locations within the core area of a species' range that were highly suitable might become too warm and therefore less suitable, turning source populations into sink populations with higher decline and extinction rates. Across species ranges, the net result of these changes in growth, decline, colonization, and extinction processes will affect their geographic distribution in different ways. However, an increase in temperature is likely to have an overall directional impact on species range shifts, because temperatures are autocorrelated in space, linking warmer conditions at lower latitudes and elevations with cooler conditions at higher latitudes and elevations. Therefore, one expects to observe poleward and upward range shifts as climate warms, even after accounting for dispersal limitations (Engler *et al.*, 2009) or biotic interactions (Araújo and Luoto, 2007). Accordingly, poleward and upward range shifts in the warming climates following the glacial recessions of the past interglacial periods have been widely reported for plants, birds, and mammals (Brown and Lomolino, 1998). For instance, Pleistocene fossils of several species of rodents have been found several thousand kilometers southward of the southern limit of their modern distribution in northern America (Graham, 1986), suggesting strong poleward shifts during the Holocene. Similarly, Pleistocene macrofossils of *Podocarpus* have been found c. 1000 m below the lower limit of their contemporary distribution on the Andean flank in western Amazonia (Cárdenas *et al.*, 2011), thus suggesting a large upward shift during the current interglacial period.

Although the expectations given temperature increase alone are relatively straightforward, it is difficult to predict how concurrent changes in other climatic factors, especially precipitation, will affect species ranges. Temperatures are negatively correlated along the latitudinal and elevational gradients and have risen globally over the past decades (IPCC, 2007b). In contrast, precipitation changes are more heterogeneous across space and time (IPCC, 2007b), leading to strong regional differences. Such regional variation in climate change, mainly due to the effect of precipitation changes on the water balance equation (balance between evapotranspiration and precipitation), may affect species ranges as well, leading to unexpected regional range shifts as climate warms globally (Crimmins *et al.*, 2011). Additionally, biotic interactions may also affect the magnitude of species range shifts as climate warms (Araújo and Luoto, 2007) with some suggestions that interactions could explain unexpected range shifts as well (Lenoir *et al.*, 2010a). Therefore, at global to continental scales, poleward and upward range shifts are likely

Figure 2 Conceptual representations of latitudinal and elevational range shifts and their mechanics under a steady-state environment (a) and under climate warming (b)–(d). In each case, the figure shows the relative importance of growth, decline, colonization, and extinction processes across the species range. For the march-, lean-, and crash-range shifts, gray shades represent conditions before a climate warming event whereas overlaying transparent colors represent shifting conditions under a climate warming event.

to be the main responses to the global increase in temperature conditions, albeit counterintuitive shifts should be expected as well at more regional scales due to regional variation in climate change and biotic interactions.

Types of Range Shifts

There are different types of range shifts. Many different terms have been used to refer to the many ways species may shift poleward or upward as climate warms, among others: leading-edge expansion, trailing-edge retraction, optimum shift, and abundance changes. Recently, a catalog of the possible species range shifts observable along a given gradient has been laid out, suggesting that observed species distribution changes are rarely complete shifts, but intermediate states in an ongoing shifting process (Maggini *et al.*, 2011). More generally, three main categories of observed range shifts can be distinguished as climate warms (Breshears *et al.*, 2008): (1) “march”; (2) “lean”; and (3) “crash” (Figures 2(b)–(d)).

- March-range shifts represent the most dynamic category of range shifts and involve dynamic edges with establishment from enhanced colonization and growth at the leading edge and mortality from enhanced decline and extinction at the trailing edge. Such dynamics driven by the edges usually lead to expansion toward higher latitudes or elevations (leading-edge expansion) or retractions from lower latitudes or elevations (trailing-edge retraction) (Maggini *et al.*, 2011). Therefore, out of this first category, one can develop several kinds of range shifts involving any combinations of expansion at the leading edge or retraction at the trailing edge, the most dynamic being a combination of both or march (Figure 2(b)). Short-lived, small-sized, and mobile species for which colonization and extinction processes occur on a relatively short time scale are likely to exhibit such dynamic range shifts. For instance, short-lived and small-sized butterfly species not strongly limited by their dispersal abilities have been reported to shift northward at both their leading and trailing edges (Parmesan *et al.*, 1999).
- Lean-range shifts involve stable edges with the optimum shifting within the existing range (Figure 2(c)). This represents the net result of enhanced growth at the highest latitudes or elevations (front edge) and decline at the lowest latitudes or elevations (rear edge) of the existing range, resulting in a shifting abundance pattern. This kind of shift might be transient and might correspond to early stages of a full shifting process (Maggini *et al.*, 2011). Long-lived, large-sized, and immobile species for which colonization and extinction processes occur on a much longer time scale than the period of observation are likely to exhibit such transient stages (time lag) across their ranges. For instance, long-lived and large-sized tree species, which tend to be strongly limited by their dispersal abilities, have been reported to shift their optimum elevation upward without shifting their range edges: persistence at the rear edge without establishment success beyond the front edge (Kelly and Goulden, 2008).
- Crash-range shifts involve stable edges and a stable optimum, but overall declines across the existing range

(Figure 2(d)). Rare species having a restricted distribution for which the degree of climate warming far exceeds their ability to shift toward suitable conditions (because of dispersal limitation and natural or anthropogenic habitat fragmentation) are likely to exhibit such changes across their ranges. Similarly, there is no possible escape for endemic species having a distribution restricted to a specific mountain summit and facing contemporary climate change. In such situations, these threatened populations may simply crash. For instance, in 1987, a multipopulation crash of the endemic golden toad of Costa Rica’s Cordillera de Tilarán has been reported to have led to the disappearance of this species (Pounds *et al.*, 1997). Additionally, species range shifts at the bottom of a food web may trigger trophic mismatch leading to multipopulation crash within the higher levels of the food web. For instance, fluctuations in plankton have resulted in a general decline in cod biomass and recruitment throughout a bottom-up control in the North Sea (Beaugrand *et al.*, 2003).

Of course, these three categories are not mutually exclusive and can be combined to develop all possible patterns of poleward or upward shifts as climate warms (Breshears *et al.*, 2008). Using the species response curve representation along one of the three geographic dimensions (Figure 2), the different combinations may affect the edges, optimum, level of abundance, or skewness of each species’ response curve, thus leading to many possible patterns of range shifts (Maggini *et al.*, 2011).

Contemporary Evidence for Latitudinal and Elevational Range Shifts

An overwhelming number of reports of latitudinal and elevational range shifts under contemporary climate change have recently appeared in the scientific literature (IPCC, 2007a). The expected poleward and upward range shifts in warming regions have been reported for many taxonomic groups across the plant and animal kingdoms (Parmesan *et al.*, 1999; Sturm *et al.*, 2001; Lenoir *et al.*, 2008; Moritz *et al.*, 2008). A recent meta-analysis (Chen *et al.*, 2011a) concluded that the distributions of species have recently shifted poleward at a median rate of 16.9 km per decade and upward at a median rate of 11.0 m per decade, which is two to three times faster than reported in a previous meta-analysis (Parmesan and Yohe, 2003). However, these global trends represent averages across considerable variation in range dynamics under climate change (e.g., Chen *et al.*, 2011a). Indeed, most of the studies that have reported the expected range shifts toward higher latitudes or elevations as climate warms globally have also detected, at a smaller frequency and to a lesser extent, species moving toward lower latitudes or elevations (Parmesan *et al.*, 1999; La Sorte and Thompson, 2007; Lenoir *et al.*, 2008, 2010a; Moritz *et al.*, 2008). In most cases, modern latitudinal and elevational range shifts have been documented by using and sometimes resurveying historical occurrence data such as museum collections and field notes (Tingley and Beissinger, 2009). These historically based studies can be divided into two main groups (Parmesan, 2006): (1) studies that directly assess

range shifts by comparing historical and modern data on a species' distribution across its entire ranges or sections of the range; and (2) studies that infer range shifts by comparing historical and modern data on species composition or abundance within local communities. The following sections cover both types of studies.

Latitudinal Range Shifts

We carried out a selective review of historically based studies documenting contemporary latitudinal range shifts. Many species across many organism groups ranging from the most simple such as plankton, algae, and lichens to the most complex such as flowering plants, birds, and mammals, across both marine and terrestrial ecosystems, have shifted their latitudinal ranges over recent decades (Table 1). Most of these contemporary latitudinal range shifts are coherent with contemporary climate change, even though some studies reported the absence of latitudinal range shifts or even unexpected latitudinal range shifts, in addition to the expected and empirically predominant poleward range shifts (Thomas and Lennon, 1999; Warren *et al.*, 2001; Hill *et al.*, 2002; Brommer, 2004; Hitch and Leberg, 2007; La Sorte and Thompson, 2007).

Most latitudinal range shifts have been documented within the animal kingdom (invertebrates, fishes, amphibians, reptiles, birds, and mammals), whereas only a handful of cases have so far been documented for plants (Table 1). Among animals, there is clear evidence of poleward range shifts through either expansion at the leading edge or retraction at the trailing edge (Parmesan *et al.*, 1999; Hickling *et al.*, 2005), or increasing and decreasing abundance at the front and rear edges, respectively (Sagarin *et al.*, 1999; Myers *et al.*, 2009). For plants, however, reported changes seem to occur principally at the leading/front edge (Smith, 1994; Sturm *et al.*, 2001; Walther *et al.*, 2005b) without much clear evidence for changes at the trailing/rear edge (Lesica and McCune, 2004), in line with conclusions from an earlier review (Jump *et al.*, 2009) on the apparent lack of latitudinal range shifts at the trailing/rear edge of plant species ranges, especially for long-lived plants such as woody species (Jump *et al.*, 2009).

Hitherto, most latitudinal range shifts have been documented in the Northern Hemisphere, with few studies focusing on the Southern Hemisphere (including Antarctica) (Table 1), consistent with previously suggested differences in observed climate-induced changes in natural and managed ecosystems between the Northern and Southern Hemispheres (IPCC, 2007a). Additionally, in the Northern Hemisphere, most latitudinal range shifts have been documented within the Arctic, boreal, temperate, and Mediterranean biomes, that is, from middle to high latitudes (Table 1). Only few studies of continental extent have covered tropical and subtropical areas below 30° latitude (Beaugrand *et al.*, 2002; Hitch and Leberg, 2007; La Sorte and Thompson, 2007). Hence, there is a striking dearth of evidence for contemporary latitudinal range shifts from areas between -60° and 30° latitude (Table 1). The paucity of evidence from the Tropics and the Southern Hemisphere (except Antarctica) may have several explanations (IPCC, 2007a): (1) a marked scarcity of good historical data

from developing countries that are suitable for resampling along the latitudinal gradient between -60° and 30° latitude; (2) a lack of taxonomical knowledge, especially in the Tropics, making it difficult to study multispecies latitudinal range shifts; (3) logistic problems, making it even more difficult to collect, access, and manage ecological data in these regions of the world; (4) the fact that mean annual temperature within the Tropics is approximately constant between -21° and 21° latitude, at any given elevation, so that little opportunity for latitudinal escape from warming exists (Colwell *et al.*, 2008); and (5) a huge imbalance of the Earth's land mass distribution with relatively little terrestrial area between -60° and 0° latitude, which probably contributes to the paucity of evidence for contemporary latitudinal range shifts for terrestrial ecosystems at these latitudes.

Elevational Range Shifts

A selective review of historically based studies documenting modern elevational range shifts was also carried out. Although most studies have reported range shifts toward higher elevations for a majority of taxa (Table 2), these studies have also reported, to a lesser extent, unexpected range shifts toward lower elevations (Lenoir *et al.*, 2010a). A few studies have even reported a general directional shift toward lower elevations for some taxonomic groups (Hickling *et al.*, 2006; Crimmins *et al.*, 2011). In Northern California, for instance, most plant species shifted downward to track regional changes in climatic water balance rather than temperature (Crimmins *et al.*, 2011). This shows that range shifts may differ not only in extent, but also in direction due to regional variation in climate change.

Contrary to latitudinal range shifts, as many elevational range shifts have been reported for plants as for animals (Table 2). Across all taxonomic groups, elevational range shifts toward higher elevations have been documented through changes either at the trailing/rear edge (Wilson *et al.*, 2005; Frei *et al.*, 2010), the leading/front edge (Hickling *et al.*, 2006; Frei *et al.*, 2010), or the core (Konvicka *et al.*, 2003; Lenoir *et al.*, 2008) of species ranges. Therefore, all possible patterns of upward shift between march- and lean-range shifts have been documented along the elevational gradient (Kelly and Goulden, 2008; Moritz *et al.*, 2008; Raxworthy *et al.*, 2008; Bergamini *et al.*, 2009). However, it has been suggested that plants, especially long-lived plants such as woody species, are more likely to lean rather than march their elevational range upward (Breshears *et al.*, 2008).

Just as for latitudinal range shifts, there is a strong imbalance of evidence for observed elevational range shifts under contemporary climate change between the Northern and Southern Hemispheres, most likely due to the higher density of mountainous area in the Northern Hemisphere relative to the Southern Hemisphere. Indeed, most elevational range shifts reports across taxonomic groups have been documented in the Northern Hemisphere, especially between 30° and 60° latitude (Table 2). Although there is a strong focus on temperate ecosystems in the Northern Hemisphere, most of the examples have been reported for subalpine, alpine, and nival ecosystems. Therefore, research efforts on elevational range shifts have been focusing on the coldest biomes (Antarctic,

^aC: continental; L: local; R: regional.

Examples of recent studies reporting, for both marine and terrestrial ecosystems, modern latitudinal range shifts of organisms at the trailing/rear edge (T/R), the core (C), or the leading/front edge (L/F) of their latitudinal range. We restricted our literature survey to studies that have explicitly used historical occurrence data to assess range shifts under modern climate change. We focused on the following two types of historically based studies (Parmesan, 2006): (1) those that directly assess range shifts by comparing historical and modern data on species distribution across their entire ranges or sections of ranges; and (2) those that infer range shifts by comparing historical and modern data on species composition or abundance within local communities. Shaded cells represent reports for marine ecosystems, whereas nonshaded cells represent reports for terrestrial ecosystems.

Arctic, and alpine) with much less research on elevational range shifts in hotter areas such as Mediterranean and tropical biomes (Table 2). However, on the contrary to the latitudinal range shifts, there is relatively many studies documenting elevational range shifts in the Tropics, for example, for plants,

insects, amphibians, and reptiles (Pounds *et al.*, 1997; Raxworthy *et al.*, 2008; Chen *et al.*, 2009; Feeley *et al.*, 2011; Juvik *et al.*, 2011). Continental-scale studies of elevational range shifts under contemporary climate change are still lacking (Table 2).

^aC: continental; L: local; R: regional.

Examples of recent studies reporting, for terrestrial ecosystems, modern elevational range shifts of organisms at the trailing/rear edge (T/R), the core (C), or the leading/front edge (L/F) of their elevational range. We restricted our literature survey to studies that have explicitly used historical occurrence data to assess range shifts under modern climate change (see **Table 1** for further explanations).

Latitudinal and Elevational Range Shifts are Lagging behind Climate Change

It is clear that contemporary climate change is driving latitudinal and elevational range shifts in species distribution worldwide (**Tables 1** and **2**). However, the magnitude of these biotic responses is unlikely to match the magnitude of contemporary climate change due to differences in speed,

magnitude, and direction between the climatic changes and the biotic responses as well as differences among species. Time lags between geographical range shifts and past climate changes have already been reported for plants and animals (Davis, 1986; Svenning and Skov, 2007; Araújo *et al.*, 2008). One way to assess the importance of such time lags in the biotic responses to contemporary climate change is to compare the magnitude of observed latitudinal and elevational

range shifts of different taxonomic groups with the magnitude of expected range shifts given climate change alone. In the French mountain forests, for instance, the core of the elevational range for plants ($n=171$ species) shifted toward higher elevations (mean: 29 m per decade $\sim 0.17^\circ\text{C}$ per decade, considering an adiabatic lapse rate of 0.6°C per 100 m in that region) only 40% of that expected simply from the observed temperature increase in that region between 1965 and 2005 (0.45°C per decade ~ 75 m per decade) (Lenoir *et al.*, 2008). For purposes of comparison, the core of the elevational range for reptiles and amphibians ($n=30$ species) in Madagascar shifted toward higher elevations (mean: 65 m per decade $\sim 0.32^\circ\text{C}$ per decade, considering an adiabatic lapse rate of 0.5°C per 100 m in that region) approximately 85% of that expected from the observed temperature increase in that region between 1984–1993 and 1994–2003 (0.37°C per decade ~ 74 m per decade) (Raxworthy *et al.*, 2008). This suggests that the magnitude of lags in range-shift responses to climate change may vary considerably among taxonomic groups (Davis, 1986).

Many different factors might be responsible for such delayed responses. Life span is obviously one of those factors. Species with shorter life spans such as insects and small mammals should be able to respond relatively fast to climate change, being delayed only a few years after a climatic event, whereas species with longer life spans, including species with slow maturation such as large mammals and many trees, should show much longer time lags, only responding to long-term climatic changes (Davis, 1986). Accordingly, it has been documented under contemporary climate change that species with shorter life cycles have shifted poleward and upward with greater magnitude than species with longer life cycles (Perry *et al.*, 2005; Lenoir *et al.*, 2008) (Figure 3). Time lags may also result from low dispersal ability. Species with limited dispersal ability, such as many plants, may not be able to rapidly colonize newly suitable climatic areas, even in the vicinity of their geographic ranges, causing time lags in their colonization of these areas (Davis, 1986). Suggestive of this mechanism, larger elevational range shifts have been reported for species with lighter diaspores as compared to species with heavier diaspores in the Italian Alps (Parolo and Rossi, 2008). Colonization of newly suitable habitats may also be delayed by competition from resident species (Davis, 1986). For instance, recruitment of *Fagus sylvatica* in southern France is delayed in grassland habitats due to its low tolerance to competition from herbaceous species (Kunstler *et al.*, 2007). Time lags in range-shift responses to climate change is furthermore likely to be most pronounced for species with small geographic ranges, as such species are often concentrated in long-term stable areas (Svenning and Skov, 2007; Araújo *et al.*, 2008), and thus likely to be particularly dispersal-limited. Linked to this idea that species with small geographic ranges might have pronounced time lags, range-shifts gaps – that is, lacking overlap between the current range and a future suitable range – are likely to occur and to increase the magnitude of these time lags if the geographic range of a species is smaller than the projected range shift under climate change (Colwell *et al.*, 2008). Crash-range shifts are a likely expectation for such species facing range-shift gaps under contemporary climate change. Finally, physiological adaptation to changing climate

Figure 3 Differential range shifts between short- (herbs, ferns, and mosses) and long-lived (trees and shrubs) plant species along the elevational gradient of the French mountain forests under contemporary climate change (Lenoir *et al.*, 2008). The drawing is from P Mouche/Terre Sauvage. Reproduced from Etienne Hurault.

conditions through either evolutionary response or phenotypic plasticity may in some cases also cause ranges to shift less than expected from climate change (Davis and Shaw, 2001).

In addition to these biotic factors, spatial features may also affect time lags in range-shift responses to climate change. Considering contemporary climate warming, closeness among spatial isotherms is probably the most obvious factor. Indeed, time lags in range-shift responses to contemporary climate change are likely to be longer in flatland areas, which offer no short-distance escapes for species facing climate change and where the velocity of climate change is expected to be much stronger, compared to mountainous terrain (Loarie *et al.*, 2009). Therefore, time lags in latitudinal-range-shift responses to climate change should be longer than time lags in elevational-range-shift responses to climate change for a given species, particularly within the tropics, where latitudinal gradients in temperature are virtually absent (Colwell *et al.*, 2008). However, Chen *et al.* (2011a) found greater elevation lags than latitudinal lags in their meta-analysis, arguing that relatively strong elevation lags may arise from topographic and topoclimatic complexity in mountainous areas. Additionally, habitat fragmentation is likely to lengthen time lags in range-shift responses to climate change. In the context of future climate change, it has been simulated that the range of forest plant species in central Belgium will lag behind climate change, especially within the most fragmented landscapes (Honnay *et al.*, 2002).

Ecological Consequences

Ecological consequences of latitudinal and elevational range shifts under contemporary climate change are numerous, affecting biodiversity, communities, and ecosystem functioning. The often mentioned potential polar and mountaintop extinctions constitute an obvious example of the likely biodiversity consequences of climate-change-induced range shifts. Indeed, species restricted to these cold extremes have nowhere

else to go to escape climate warming. Therefore, their potential habitat is shrinking through a general reduction in surface area. Such range-restricted species may experience severe range contractions and may be the first groups in which species have already been driven to extinction by contemporary climate change (Parmesan, 2006). Endemic species restricted to low and isolated mountains in the temperate and tropical zones are especially threatened with extinction as a consequence of range-shift responses to climate warming (Krajick, 2004), for example, alpine endemics restricted to summits of low mountains lacking nival belts or subalpine endemics restricted to summits of low mountains lacking alpine and nival belts. In the long run, these low mountains may act as climatic traps for range-restricted species facing climate warming (Forero-Medina *et al.*, 2011). However, contemporary climate change at these high latitudes (poles) and elevations (mountaintops) also allow the immigration of new species from lower latitudes and elevations, which generally host a higher diversity, with the net result of these contemporary range shifts being a gradual increase in species richness toward the poles and mountain summits (Grabherr *et al.*, 1994; Walther *et al.*, 2005a), though time lags in range-shift responses to climate change are expected and may lead to both extinction debt and immigration credit (Jackson and Sax, 2010). Not only gradual increase in species richness is expected toward the poles and mountain summits as a net result of contemporary range shifts, but also lowland biotic attrition may occur in the Tropics as a net result of range contractions and extinctions without any possibility for compensation, contrary to higher latitudes, where immigrants can come from lower latitudes (Colwell *et al.*, 2008). Similar attrition may also occur in extra-tropical lowland areas due to migrational lags if source pools are distantly located (Svenning and Condit, 2008).

Communities may also be strongly affected by contemporary climate-driven range shifts, mainly throughout changes in species composition. Indeed, shifting species might be forced to interact with a new set of resident species from the recipient community, thus leading to community reorganization (Walther, 2010). Such new species assemblages may result in the formation of nonanalog communities, that is, communities that are different in species composition from any communities present at a selected reference point in time (Keith *et al.*, 2009). Range-shift-induced community reorganization may have important ecological consequences. For example, plant community homogenization among alpine summits has been reported in the Alps (Jurasinski and Kreyling, 2007) as a consequence of the upward shift of alpine plant species in the same region (Walther *et al.*, 2005a). However, such community reorganization occurs not only “horizontally,” that is, within the same taxonomic group, but also “vertically,” that is, across taxonomic groups and trophic levels, and, thus, could also strongly affect ecological networks.

Climate change effects on ecological networks could also have consequences for ecosystem functioning (Walther, 2010). For instance, species range shifts within a given trophic level may induce trophic cascades through bottom-up or top-down effects. An empirical example is the impact of sea surface warming on the poleward shift of phytoplankton in the Northeast Atlantic, which has been reported to propagate up

the food web throughout bottom-up control on copepod herbivores and zooplankton carnivores (Richardson and Schoeman, 2004). In this case, the tight trophic coupling between phytoplankton, copepods, and zooplankton carnivores allows a preservation of the main functions ensured by this marine food web. However, such ecosystem functioning can be disrupted if the coupling between interacting species is too loose or if interacting species respond differently to climate change. The most striking evidence of such disruptions can be found in reports of pest outbreaks after range shifts of pest species released from the top-down control of their predators. As a typical example, recent range shifts of the pine processionary moth, *Thaumetopoea pityocampa*, has caused major outbreaks in Europe by switching hosts (Battisti *et al.*, 2005). Ecological consequences of these large-scale herbivore outbreaks may involve changes in the carbon sequestration budgets. Other important implications of species range shifts for ecological networks and ecosystem function concern the loss or gain of new functional types. Indeed, some ecosystems are likely to lose or gain functions as a result of species range shifts and community reorganization. In northern Arizona, recent vegetation shifts resulting from extreme mortality of pinyon, *Pinus edulis*, have affected the structure of the pinyon-juniper woodland, causing loss of avian seed dispersers, the disappearance of ectomycorrhizas specific to pinyon, and above- and below-ground competitive release of juvenile trees (Mueller *et al.*, 2005). In parallel, the recent expansion of shrubs in the Arctic (Sturm *et al.*, 2001) is changing the physiognomy of the arctic vegetation by allowing shrubs, a new functional type, to establish, with likely cascading ecological consequences. Indeed, it is suggested that increased vegetation cover in the Arctic may not only provide food resources for invasions of new animal species such as moths, already now causing outbreaks in the Arctic, but also cause ecological changes that may affect the Earth's climate itself, notably via changes in regional land-atmosphere greenhouse gas balances and carbon budgets (Post *et al.*, 2009).

Conservation Implications

Latitudinal and elevational range shifts and their resulting ecological consequences constitute a major challenge for conservation biology. Many recommendations for climate change adaptation strategies for biodiversity conservation have been recently listed in a literature review (Heller and Zavaleta, 2009). Here the focus is on two heavily discussed management recommendations: the traditional habitat-management recommendations and the controversial species-management recommendations. Most management recommendations so far have focused on conserving or restoring habitat quality to enhance species survival. The top-most-cited recommendation for biodiversity conservation under climate change is to increase habitat connectivity by establishing corridors, removing barriers for dispersal, and planning reserves close to each other so as to re-create series of stepping stones of high-quality habitats and increase possibilities for species range shifts (Heller and Zavaleta, 2009). Other habitat-management recommendations include creating and managing buffer zones within and around nature reserves (Heller and Zavaleta, 2009).

For instance, topographic heterogeneity is associated with low climate change velocity (Loarie *et al.*, 2009) and should enhance the long-term conservation capacity of nature reserves (Ackerly *et al.*, 2010) by providing short-distance escapes for species facing climate change (Scherrer and Körner, 2011). However, depending on the magnitude of climate change and the degree of topographic heterogeneity within species ranges, topographic heterogeneity may just temporarily buffer biodiversity before starting to act as a climatic trap by increasing spatial isolation and extinction risks (Forero-Medina *et al.*, 2011).

Nevertheless, it is also increasingly clear that the traditional habitat-management recommendations may be insufficient for safeguarding biodiversity from climate-driven extinctions, and therefore species-management recommendations are being proposed, notably assisted migration (also called assisted colonization or managed translocation) (Thomas, 2011). Among others, dispersal-limited or small-range species might not be able to be saved by more traditional habitat-management recommendations, such as increasing landscape connectivity to enhance species migration (Heller and Zavaleta, 2009; Thomas, 2011). Assisted migration is controversial, especially given the fear that translocated species could increase the risk of native species extinctions in their new recipient habitats (Ricciardi and Simberloff, 2009). However, for climate-threatened, dispersal-limited, or small-range species, it has been suggested that translocation might be the only successful management strategy, and therefore should be implemented provided that risks of extinction to native species in recipient habitats are small (Morueta-Holme *et al.*, 2011; Thomas, 2011). To help managers in making decisions between habitat- and species-management recommendations, a decision framework has already been proposed for assessing when species translocations are possible (Hoegh-Guldberg *et al.*, 2008).

Future Challenges

Despite the increasing number of studies documenting latitudinal and elevational range shifts under contemporary climate change, a better understanding of current range shifts is still needed for developing well-founded predictive models of future range shifts. More research efforts are needed to better understand climate change effects on species ranges at low latitudes and especially within the Tropics, the most species-rich part of the world and the area hosting most threatened taxa (IUCN, 2004). So far, evidence of recent species range shifts in the Tropics have been mostly documented along elevational gradients (Pounds *et al.*, 1997; Raxworthy *et al.*, 2008; Chen *et al.*, 2009; Feeley *et al.*, 2011; Juvik *et al.*, 2011) with at most a handful of reports for plants (Feeley *et al.*, 2011; Juvik *et al.*, 2011). Although the magnitude of climate warming varies geographically, most tropical areas have warmed just as much as temperate areas (IPCC, 2007a). Furthermore, small changes in temperature conditions in the Tropics may have much stronger biotic impact than similar changes in temperate areas. Notably, recent research into the thermal tolerance of terrestrial insects shows that tropical insects are closer to their maximum thermal tolerance than temperate insects (Deutsch *et al.*, 2008), suggesting that tropical species and

their ranges may be particularly sensitive to climate warming. Importantly, crash-range shifts are therefore more likely in the Tropics (Pounds *et al.*, 1997) than elsewhere. Even more alarming, there do not exist biodiversity source pools now living in hotter places (as such areas do not exist) that are available to replace climatically displaced or declining species in tropical lowland ecosystems, potentially leading to lowland biotic attrition in the lowland tropical areas (Colwell *et al.*, 2008), with unknown consequences for ecosystem functioning.

Another future challenge is to achieve a better understanding of the mechanisms involved in species range shifts. Notably, it is still unresolved how the different population dynamics involved at both the range edges is driving species range shifts. Are colonization and establishment processes occurring more rapidly at the front edge of a species' range than mortality and extinction processes at the rear edge? For instance, the rear edge of a species' range is likely to host a relatively high genetic diversity due to selection pressure over time (Hampe and Petit, 2005), thus having a high potential for delaying range contractions under contemporary climate change. Therefore, rear edges may be disproportionately important for the survival and evolution of species (Hampe and Petit, 2005). Surprisingly, fewer studies have focused on contemporary range shifts at the trailing edge of species' ranges in comparison to the leading edge. This lack of focus on range shifts at the trailing edge of species' ranges is even more important along the latitudinal gradient for long-lived plants such as woody species (Jump *et al.*, 2009). In short, there is also an urgent need to improve our understanding of species range shifts at the trailing edge of species' ranges. Additionally, the strong variation in the magnitude of contemporary range shifts among species raises questions about the underlying reasons and whether the magnitude of shifts is linked to species traits. A recent study focusing on the relationship between species traits and the magnitude of recent shifts at the leading edge found low explanatory power, suggesting that trait-based range shift forecasts face several challenges (Angert *et al.*, 2011). Finally, the occurrence of unexpected range shifts (such as stasis or even downslope shifts) is an understudied phenomenon of high importance for predicting range responses to future climate change (Lenoir *et al.*, 2010a). This is linked to our current lack of knowledge regarding the effect of biotic interactions and dispersal constraints on species distributions.

Addressing these challenges will allow the development of improved predictive models of future range shifts. Indeed, with exactly this aim, recent discussions have raised the need for improving the field of species distribution modeling (SDM) by developing more mechanistic, hybrid approaches such as coupling stochastic population models with dynamic bioclimatic habitat models (Keith *et al.*, 2008) or by better accounting for nonclimatic factors and ecological complexity, notably biotic interactions and dispersal constraints (Morin and Lechowicz, 2008).

Latitudinal Gradients of Biodiversity

Michael R Willig and Steven J Presley, University of Connecticut, Storrs, CT, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Alpha (α) diversity The diversity of species, often estimated as species richness, within a local community or site.

Beta (β) diversity The degree of turnover in species (and changes in their abundances) among communities or sites along a gradient or within a larger area.

Biodiversity A multidimensional concept embodying various dimensions (e.g., taxonomic, functional, phylogenetic, and genetic) that characterize variability of the biota in time or space.

Functional biodiversity A characterization of a biota that relates to variation in the importance (e.g., relative abundance, biomass, and relative frequency of occurrence) and functional attributes of taxa, and estimated by components such as guild richness, evenness, dominance, and diversity.

Gamma (γ) diversity The diversity of species, often estimated as species richness, in a larger area as a consequence of both α - and β -diversity.

Phenetic biodiversity A characterization of a biota that relates to variation in phenotypic characteristics (traits) of taxa, and estimated by components that reflect the size of

the phenotypic hypervolume defined by constituent taxa, or the dispersion of phenotypes within that hypervolume.

Phylogenetic biodiversity A characterization of a biota that embodies evolutionary history and relates to variation among taxa based on their importance (e.g., relative abundance, biomass, and relative frequency of occurrence) and relationships by descent, including components, such as mean and variance of divergence rates or mean and variance of species ages.

Scale dependence A condition in which either the form or the parameters of a relationship between two variables (e.g., richness and latitude) is contingent on spatial or temporal attributes.

Species diversity A component of taxonomic biodiversity that reflects the variety of organisms in an area and that includes two components, species richness and species evenness (the degree to which all species have the same proportional abundance).

Taxonomic biodiversity A characterization of a biota that relates to variation in the importance and taxonomic identities of taxa, and estimated by components such as species richness, evenness, dominance, diversity, and rarity.

Introduction

Latitudinal gradients of biodiversity are biogeographic patterns that define the way in which components of taxonomic, phylogenetic, functional, genetic, or phenetic dimensions change with latitudinal position on the surface of the earth. By far, most research has considered only taxonomic biodiversity, generally species richness. Consequently, much of this article considers latitudinal gradients in species richness. The general pattern is for species richness to increase from polar to tropical regions (Willig *et al.*, 2003; Hillebrand, 2004), regardless of the taxonomic affiliation of organisms (e.g., mammals, fishes, insects, and plants) or geographic setting in which they occur (e.g., Africa, South America, and the Atlantic Ocean). This is true for extant organisms (Figure 1) as well as for those organisms alive during the past 70 million years (Figure 2). An increase in species richness with decreasing latitude is the pattern generally observed at three spatial scales, including the level of broad climatic zones (Figure 3), assemblages occupying arbitrary geographic subdivisions (i.e., quadrats or bands) of the earth's surface (Figure 4), and local ecological communities (Figures 4 and 5). Nonetheless, not all taxa increase with decreasing latitude in the same fashion, and a few groups do not even exhibit the general pattern of a latitudinal increase in richness towards the tropics. Moreover, considerable controversy surrounds the mechanisms that affect latitudinal patterns in richness, with ecological, evolutionary,

historical, and stochastic processes (Table 1) championed as the cause(s) of observed gradients (Rohde, 1992). Indeed, many of the mechanisms are circular or unsubstantiated by empirical data.

Context

Since the voyages of Darwin and Wallace, biologists have been fascinated with the high species richness of tropical regions compared to those in temperate or boreal zones. Indeed, this fascination with tropical species richness catalyzed in many ways the conceptual development of the theory that currently constitutes modern ecology. Moreover, increasing concern about the loss of species, especially in tropical regions, has led to the rapid development of the science of conservation biology. Documenting the way in which biodiversity varies across the globe and understanding the mechanisms that produce such variation are critical steps in the design of global conservation strategies and the implementation of regional management plans.

The mid-1950s to early 1960s saw the emergence of rigorous quantification of broad-scale relationships between species richness and latitude (Fischer, 1960). Within the next 25 years, scientists convincingly had documented the ubiquity of gradients in which species richness increased toward tropical areas. Similar gradients (Figures 3 and 4) were

Figure 1 Species richness gradients in Canada and the US for trees (a), mammals (b), amphibians (c), and reptiles (d). Contour lines connect localities with approximately equal species richness. Reproduced from Currie DJ (1991) Energy and large-scale patterns for animal- and plant-species richness. *American Naturalist* 137: 27–49.

documented for the richness of higher taxonomic groups (e.g., genera, families, and orders). Indeed, the increase in species richness for terrestrial and marine environments was quantified successfully for a wide variety of taxonomic groups, such as mammals, birds, reptiles, amphibians, fish, tunicates, crustaceans, mollusks, brachiopods, corals, foraminiferans, and vascular plants. Nonetheless, some taxa representing lower levels in the systematic hierarchy (i.e., orders or

families) were notable exceptions in having maximal richness in polar (e.g., seals, penguins, and sandpipers) or temperate zones (e.g., voles, salamanders, ichneumonid wasps, and coniferous trees). Caution must be employed in considering such exceptions because other groups of equivalent rank within the same higher taxon often are restricted to lower latitudes, and the higher taxon exhibits a tropical maximum in species richness.

Figure 2 Latitudinal gradient in fossil species richness for marine Foraminifera from approximately 70 million years ago. Modified from Rosenzweig ML (1995) *Species Diversity in Space and Time*. Cambridge, MA: Cambridge University Press.

Figure 3 Generic and species richness of tunicates in each of the five major climatic regions defined by latitude and arranged from northern-most latitudes, through the tropics, to southern-most latitudes. Modified from Fischer AG (1960) Latitudinal variations in organic diversity. *Evolution* 14: 64–81.

Latitudinal gradients in other aspects of taxonomic biodiversity (e.g., species or generic evenness, diversity, dominance, and rarity) as well as in other dimensions of biodiversity (e.g., functional, phenetic, and phylogenetic) have received increasing attention in the past decade. This nascent field of investigation is ripe for exploring the form of gradients, the

mechanisms that affect them, and the degree to which they are associated with each other.

Patterns

In the context of this article, a gradient implies a gradual change in biodiversity with a gradual change in latitude. In an unambiguous fashion, the form of that pattern is the precise mathematical or statistical relation that describes how biodiversity changes with latitude. As a consequence, three considerations are important in assessing patterns: the general shape of the curve (e.g., symmetry, kurtosis, or linearity), the parameters that characterize the relation, and the degree to which the fit of empirical data to the predicted curve is equivalent to the north and south of the equator. Knowledge of these three aspects of gradients suggests the kinds of causal mechanisms that are in operation. In addition, it facilitates comparison of gradients among taxa within the same geographic domain (Figure 1; birds versus mammals versus reptiles versus amphibian in North America) as well as comparisons among different geographic domains for the same taxon (Figure 4; North American versus South American for mammalian orders).

Patterns are often scale dependent, with particular mechanisms more likely operating at some spatial scales than at others. Consequently, patterns will be elucidated for each of two foci: biotic assemblages occupying broad areas and ecological communities occupying local sites. These scales are intimately associated with each other. In part, the species richness of regions, biomes, or climatic zones is a consequence of the species richness that is accumulated within constituent local communities. Similarly, the species richness and composition of local communities are affected by the set of taxa that constitute regional species pools.

Assemblages

Most of the empirical research concerning the relationship between biodiversity and latitude considers species richness and has been done using arbitrary sampling units that were based on (1) latitudinal bands, (2) quadrats of fixed area, or (3) quadrats of unequal area defined by lines of longitude (meridians) and latitude (parallels). Alternatively, research has focused on the species richness of biomes or broad latitudinally defined climatic zones. Because the area of any sampling unit may have as large or larger effect on variation in species richness than does its latitude, it is critical to understand how area may affect latitudinal patterns in different ways, depending on the method or approach (see Scheiner *et al.*, 2011).

Generally, analyses of quadrats defined by meridians and parallels are inferior to those based on other sampling units because such quadrats differ in area in a systematic fashion and bias quantitative conclusions. As meridians converge toward the poles, the size of the quadrats becomes smaller. Consequently, any attempt to control for variation in richness among quadrats as a consequence of area will remove at least some of the effects of latitude as well. This confounding effect compromises the detection of pattern across broad latitudinal gradients.

Figure 4 Differential contribution of mammalian orders to the latitudinal gradient of species richness in the New World based on data from 5° latitudinal bands. Reproduced from Kaufman DM (1995) Diversity of New World mammals: Universality of the latitudinal gradients of species and bauplans. *Journal of Mammalogy* 76: 322–334.

Analyses based on latitudinal bands also must control the effect of area because the width of a continent is not constant at all latitudes. A variety of methods have been used to compensate for this problem. Importantly, care must be employed when the area of bands varies in a systematic fashion with latitude because of the shape of the continent (e.g., progressive decreases in area with decreasing latitude in North America versus progressive increases in area with decreasing latitude in South America). In such cases, analyses based on bands may be plagued with the same confounding effects as those for analyses based on quadrats defined by meridians and parallels. Indeed, if classical statistical techniques are used to control for the effect of area in bands defined by 5° meridians in North America, the areal relationship is contrary to both common sense and ecological theory in that species richness increases as area decreases. Subsequent assessment of latitudinal effects may be severely compromised because the width of North America decreases as latitude decreases. Hence, adjusting the latitudinal gradient to account for area also removes an appreciable latitudinal effect. Nonetheless, if continental shape does not confound the effects of latitude and area, then regression techniques hold great promise, especially if appropriate nonlinear approaches are taken to adjust species richness in accord with species area theory (i.e., adjust richness of bands to a common area based on nonlinear regression of nested quadrats within each band).

Quadrats of fixed size also have been used to analyze broad-scale patterns of diversity. Nonetheless, variation in species richness among sampling units could still be a consequence of area, at least partially, when quadrats occupy coastal positions along continental borders. Adjusting for area in these cases may obscure the effects of rapid transition zones in terrestrial communities as they approach land–sea margins. Hence, the consensus is to not consider quadrats unless they are full of land. Subsequent variation among quadrats that is

due to latitude can be assessed through a variety of statistical models. However, here too it is important to note that patterns are scale dependent. That is, the pattern detected for quadrats encompassing 100 km² could be quite different from those at 10,000 km². The importance of scale dependence in latitudinal studies has been emphasized increasingly during the past decade (e.g., Lyons and Willig, 2002).

Much of the early literature on latitudinal gradients in biodiversity was based on the species richness of broadly defined climatic zones (e.g., north polar, north temperate, tropical, south temperate, and south polar) or geopolitical units (e.g., countries, states, and provinces). Taxonomic richness was documented to increase from polar to tropical regions (Figure 3). Even when values for richness were not adjusted for the areal extent of geopolitical regions (e.g., snake species in Argentina, ant species in the Americas, and breeding bird species in the Americas), the polar to tropical gradient was obvious. Nonetheless, controversy currently surrounds the interpretation of such data when the focus is on broad climatic zones associated with latitude. Some suggest that the increase in diversity with decreasing latitude primarily is a result of more tropical regions having larger areas than their extratropical counterparts. In contrast, others suggest that extratropical areas are often larger but have fewer species than their more tropical counterparts, suggesting that latitudinal correlates other than area are the driving forces behind the gradient (see Geographic Area Hypothesis).

Ecological Communities

The way in which latitudinal variation in biodiversity at broad spatial scales (i.e., γ -scale) is related to patterns of biodiversity at the level of local communities (i.e., α -scale) is unclear. In part, this is because the geographic boundaries of a community are difficult to designate and are ultimately arbitrary

Figure 5 Latitudinal gradients of the taxonomic dimension of biodiversity – species richness (a), Shannon diversity (b), Camargo evenness (c), and Berger–Parker dominance (d) – within local communities for bats from throughout the New World. When regression models are significant, the contribution of linear (b_1) or quadratic (b_2) terms are indicated by superscripts (NS, $p > 0.05$; *, $0.05 \geq p > 0.01$; **, $0.01 \geq p > 0.001$; ***, $p > 0.001$); percent variation in a component of taxonomic biodiversity that is related to latitude is quantified by R^2 . Reproduced from Stevens RD and Willig MR (2002) Geographical ecology at the community level: Perspective on the diversity of New World Bats. *Ecology* 83: 545–560.

decisions. Moreover, until recently, little was known about the composition of local communities in tropical regions, making assessment of broad-scale latitudinal patterns of biodiversity a premature endeavor at the community level. Finally, it is unlikely that a single research scientist can gather sufficient data across many sites to assess latitudinal gradients in biodiversity with sufficient power to distinguish pattern from noise. Hence, compositional data must be compiled from the work of many different individuals, who often use different methods, designs, and sampling intensities, to quantify the gradient in a meaningful way. Concern regarding adequate sampling within a community must be tempered by the realization that community composition has a temporal dynamic. Communities represent suites of populations with the potential to interact, and thus must be constrained to some extent by both time and space. Sampling regimes that extend over protracted periods

of time (e.g., decades or longer) may have inflated estimates of richness and inaccurate assessments of species composition. Nonetheless, recent progress in this regard allows quantitative evaluation of patterns in a rigorous way, at least for some taxonomic groups.

When care is taken so that a local community is delimited as a geographic area in which constituent species have a high likelihood of interaction and of affecting each others' demographics, it is clear that species richness increases from polar through temperate to tropical regions. For example, data for volant mammals (bats) from 32 local communities (Stevens and Willig, 2002) that met rigorous standards for inclusion in analyses (i.e., well-delimited local areas must have been sampled intensively for at least 1 year to include all seasons in which species are active) clearly exhibit a latitudinal gradient of increasing richness with decreasing latitude (Figure 5(a)).

Table 1 Mechanisms potentially affecting the latitudinal gradient in species richness

Circular	Empirically unsubstantiated
Competition	Environmental stability
Mutualism	Environmental predictability (contingency)
Predation	Productivity
Epidemics	Abiotic rarefaction
Biotic spatial heterogeneity	Physical heterogeneity
Population size	Angle of the sun above the horizon
Niche width	Area
Population growth rate	Aridity
Patchiness	Seasonality
Epiphyte load	Number of habitats
Host diversity	Rapoport's rule (range size gradient)
Harshness	Ecological time
	Evolutionary time
	Temperature dependence of chemical reactions
	Solar energy
	Evolutionary speed
	Stochastic placement of species ranges

Species richness of nonvolant taxa (tetrapods) in mammalian communities from North America also shows a significant increase from polar to tropical regions (Figure 6; Kaufman, 1998).

Beyond species richness, taxonomic biodiversity has a number of other interrelated components such as evenness, diversity, dominance, and rarity. Components other than richness arise by weighting the presence of species by some measure of importance such as relative abundance, relative biomass, or relative frequency of occurrence. Moreover, each component can be estimated by different indexes that differ in the precise mathematical ways in which presence is weighted by importance. Richness is the number of species in a community; it can be equal to the empirical value or can be estimated via a variety of more complicated techniques such as extrapolation or rarefaction. Evenness represents the extent to which the distribution of individuals among species is equitable. Diversity is a composite metric, comprising aspects of richness and evenness. Dominance is the extent to which a single taxon represents the largest proportion of individuals in a community. Rarity is a measure of the number of taxa below some threshold level of abundance (e.g., the number of species with less than the average proportional abundance $[1/S]$ in a community of S species). The extent to which each of these components of taxonomic biodiversity exhibits a latitudinal gradient has not been explored for most groups of plants, animals, or microbes. In contrast, the comprehensive analysis of Stevens and Willig (2002) characterized taxonomic biodiversity of New World bat communities based on 14 different indexes representing species richness (3 metrics), evenness (4 metrics), dominance (3 metrics), and diversity (4 metrics). They demonstrated that spatial variation in richness was independent of spatial variation in evenness. Moreover,

Figure 6 Latitudinal gradient of species richness for mammalian tetrapods in local communities in North America. Reproduced from Kaufman DM (1998) *The Structure of Mammalian Faunas in the New World: From Continents to Communities*. Unpublished PhD Dissertation, University of New Mexico, Albuquerque.

they documented strong latitudinal gradients in species richness and diversity, but the absence of such gradients in species evenness or dominance (Figure 5).

Many factors (e.g., productivity, competition, predation, and disturbance) have been suggested as the dominant forces affecting the composition and structure of local communities. Early theoretical and empirical work stressed the role of deterministic factors such as competition in molding community attributes. Subsequent focus on the distinction between equilibrial and nonequilibrial communities cast doubt on the universality of deterministic mechanisms in general and competition in particular, and raised serious questions about the degree to which local communities were saturated by species. Indeed, variation in the degree to which local communities attain equilibrial richness may contribute strongly to the latitudinal gradient in biodiversity. The latitudinal progression from polar to tropical regions may represent a gradient in the degree to which stochastic density-independent mechanisms or biotic interactions dominate the forces affecting the abundance of local populations and the composition of local communities. Specifically, the species richness of a community may be a consequence of the severity, variability, and predictability of local environmental conditions. Low predictability and harsh conditions predispose communities to be regulated by abiotic parameters and to have low diversity. High predictability and conditions that are clement favor high diversity. To the extent that high solar insolation and warm temperatures represent favorable conditions, and low intra-annual variation in temperature and

rainfall represent predictable conditions, tropical communities should be more species rich than their extratropical counterparts. In essence, many of the factors that affect elevated richness at the local scale likely contribute to enhanced γ -diversity of regions as well.

Hierarchical Configuration of Biodiversity

The hierarchical configuration of biodiversity is an inherently scale-dependent phenomenon that influences the form and parameterization of latitudinal gradients, as well as the relationship between patterns at the local (α) and regional (γ) scale. Indeed, turnover among local sites in species composition contributes to the disparity between biodiversity at local and regional scales, is ostensibly related to habitat heterogeneity, and can be conceptualized via an additive model or a multiplicative model. Unfortunately, considerable confusion and controversy has characterized the discussion of such issues, but a consensus is emerging concerning the meaning and measurement of β -diversity in ecological and biogeographic contexts (see Tuomisto, 2010), with the multiplicative model rather than the additive model gaining ascendancy provided that metrics are adjusted to measure "true diversity" (*sensu* Jost, 2007). Moreover, such hierarchical decomposition can be applied to metrics other than species richness, such as species diversity, evenness, dominance, and rarity. In such a context, β -scale metrics may be considered to estimate the number of distinctive compartments or assemblages along the gradient.

Regardless of model, additive or multiplicative, the increase in species richness from polar to tropical latitudes for assemblages (γ -component) can be a consequence of a gradient in species richness at the α -level, β -level, or both. The β -component of species richness increases toward the equator for a variety of groups of mammals, birds, shallow water bryozoans, trees, and herbaceous plants (summarized in Willig *et al.*, 2003). The exact form of the increase may differ among taxa or between continents. For New World bats, the rate of increase in species richness from extratropical to tropical communities (α -level) is much less than the comparable rate for regional species pools (γ -scale), suggesting that the β -component consistently increases with decreasing latitude (Stevens and Willig, 2002). In contrast, the β -component of species richness remained more or less constant below 30° N latitude for nonvolant mammals in North America (Kaufman, 1998). Moreover, the turnover in species composition between quadrats within elevational bands was independent of latitude in both North and South America (Willig and Gannon, 1997).

Multiple Dimensions of Biodiversity

The past decade has witnessed increasing interest in understanding how functional, phylogenetic, genetic, or phenetic biodiversity responds to spatial, temporal, or environmental variation, and whether such gradients are any different than those produced by parallel gradients in species richness. Research on latitudinal gradients of multiple dimensions of biodiversity is in its infancy, but recent investigations have quantified these gradients, and have shown that they are of

multiple forms and are not wholly explicable by gradients in richness. For ease of exposition, the authors illustrate the state of knowledge for latitudinal gradients of functional, phenetic, and phylogenetic biodiversity based on a comprehensive suite of analyses for 32 communities of New World bats (see Ecological Communities) for which a strong linear increase in species richness accompanies a decrease in latitude (Figure 7(a)).

The functional dimension of biodiversity can be evaluated based on the consideration of functional traits or on the assignment of species to guilds based on considerations of natural history (e.g., foraging mode and diet). Regardless, measures of functional biodiversity evaluate variation in characteristics of a biota that relate to ecosystem processes, species interactions, or functional characteristics of a community. A number of indexes of functional biodiversity can be estimated by weighting guilds by some aspect of importance such as relative species richness, abundance (regardless of species), or biomass (regardless of species), giving rise to guild evenness, diversity, or dominance. Nonetheless, the simplest index is guild richness, the empirical number of recognized guilds in a community. Like the latitudinal gradient of species richness, the latitudinal gradient of guild richness of New World bats (Stevens *et al.*, 2003) is strong, and generally increases from extratropical to tropical latitudes; however, the form of the relationship is markedly nonlinear (Figure 7(b)). Of course, species-rich communities should contain more guilds by chance alone (i.e., selection effects). Simulation analyses can evaluate if empirical gradients of guild richness are essentially a consequence of the latitudinal gradient of species richness. Such an approach randomly selects from an appropriate species pool the same number of species as occurs in an empirical community, repeats the random selection process for all empirical communities, estimates parameters of a randomly generated latitudinal gradient in guild richness, and repeats the simulation a sufficient number of times to create a probability density function of parameter values for a gradient created by chance alone. An observed gradient in guild richness is significant if empirical parameter estimates occur in the extreme tails of the generated probability density functions. New World bat communities exhibited a strong and significant latitudinal gradient of guild richness based on such approaches when the suite of bats in the continental New World composed the species pool for each community. In contrast, when each species pool for a community was regional in composition (i.e., each community had a unique species pool defined by the suite of taxa whose geographic distributions overlapped the site), the empirical latitudinal gradient of guild richness was not different than expected given the observed variation in the composition of regional species pools and the species richness of the community. These same approaches were used to assess latitudinal gradients of guild evenness, diversity, and dominance. Guild diversity and dominance significantly, but nonlinearly, increased and decreased toward the tropics, respectively. Like the situation for guild richness, the gradients in guild diversity and dominance were different than those arising from chance alone when considering hemispheric species pools, but no different than expected by chance alone when considering the regional species pool. In contrast, guild evenness evinced

Figure 7 Latitudinal gradient of taxonomic biodiversity (species richness, a), functional biodiversity (guild richness, b), phenetic biodiversity (nearest neighbor distance, c), and phylogenetic biodiversity (mean rate of sequence divergence, d) within local communities for bats from throughout the New World. Reproduced from Stevens RD and Willig MR (2002) Geographical ecology at the community level: Perspective on the diversity of New World Bats. *Ecology* 83: 545–560; Stevens RD, Cox SB, Strauss RE, and Willig MR (2003) Patterns of functional diversity across an extensive environmental gradient: Vertebrate consumers, hidden treatments and latitudinal trends. *Ecology Letters* 6: 1099–1108; Stevens RD, Willig MR, and Strauss RE (2006) Latitudinal gradients in the phenetic diversity of New World bat communities. *Oikos* 112: 41–50, and Stevens RD (2006) Historical processes enhance patterns of diversity along latitudinal gradients. *Proceedings of the Royal Society B* 273: 2283–2289.

random variation with respect to latitude, a pattern expected due to chance, regardless of the nature of the species pool. Taken together, these results suggest that processes, evolutionary or ecological, that determine the composition of regional faunas strongly influence the latitudinal gradient in functional biodiversity.

The phenetic dimension of biodiversity can be evaluated based on considerations of a suite of phenotypic or morphological characteristics. Phenotypic characteristics of species have a profound effect on their ecological attributes, and provide an integrated view of ecological relationships over space or time. Different components of phenotypic biodiversity then relate to aspects of the volume (equivalent to richness) or dispersion (equivalent to evenness) of species

within a multidimensional space defined by the phenotypic characteristics of species in a community. If the phenetic characteristics relate to foraging mode or diet, such an analysis could be construed as a trait-based assessment of functional biodiversity. More generally, the selection of phenotypic characteristics to be included in analyses determines the kind of phenetic biodiversity that is reflected in resultant components. By measuring a suite of external and cranial characteristics related to the size and foraging apparatus of bats (e.g., skull measurements related to the size and hardness of prey, or wing measurements related to aerodynamic ability), Stevens *et al.* (2006) characterized a number of aspects of the phenetic dimension of biodiversity. For example, they showed that mean nearest neighbor distances decreased significantly and

linearly toward the tropics (Figure 7(c)), and this trend was different from that expected given the richness of communities and the composition of the hemispheric species pool, but no different than expected by chance given the richness of communities and the composition of site-specific regional species pools. Again, historical factors affecting regional species pools have a great impact on gradients of phenetic biodiversity.

The phylogenetic dimension of biodiversity reflects the evolutionary history embodied in a community (e.g., the distribution of taxon ages or the magnitude of relatedness within a community). A variety of metrics then estimate different aspects of that evolutionary history, and each species contribution to those estimates can be weighted by the aspects of importance (e.g., relative abundance and relative biomass). Stevens (2006) estimated a number of different components of the phylogenetic dimension of biodiversity for New World phyllostomid bat communities. He documented a number of distinctive gradients based on the average and variance in the rate of sequence divergence, as well as on the average and variance in the relative ages of taxa. For example, the mean rate of sequence divergence in a community decreased from extratropical to tropical latitudes, but did so in a nonlinear manner (Figure 7(d)). Moreover, he showed that the latitudinal gradient in phylogenetic diversity was different from that expected given the latitudinal gradient in species richness and the composition of the hemispheric species pool. These results suggest that significant historical events influence contemporary gradients in biodiversity with the most derived and least variable taxa occurring at the periphery of the geographic range of the family (i.e., in extratropical areas), providing support for the concept of niche conservatism.

Mechanisms

A grand proliferation of hypotheses (Table 1), along with subsequent *a posteriori* modifications, is a characteristic feature of the literature concerning the relationship between biodiversity and latitude. A variety of factors contribute to this. Each of these hypotheses represents a conceptual model with only qualitative predictions. As with much of macroecological research, broad-scale data concerning the distribution of species is not available for many taxa. Manipulative experiments designed to disentangle the effects of competing hypotheses are not feasible or ethical. In addition, the inherent geographic factors that might affect richness are often correlated so that efforts to remove the effect of one to assess the other can lead to spurious results due to the confounded nature of the mechanisms.

Indeed, almost all hypotheses provide only a general qualitative prediction that richness should increase toward the tropics. The hypotheses represent conceptual models that lend insight into how nature could operate, but do not generate unique predictions based on direct features of the gradient that allow conclusive elimination of competing hypotheses in the sense of strong inference. Moreover, many hypotheses are circular in nature and the indirect predictions that they make about latitudinal gradients have not been examined comprehensively from an empirical perspective. In addition, some hypotheses only pertain to particular taxa or ecological groups, so that they are not applicable universally.

Rather than elucidating the score of extant hypotheses, which has been done to greater or lesser extents elsewhere (Rohde, 1992; Rosenzweig, 1995), an exposition of selected hypotheses that have generated debate in the contemporary literature follows. These hypotheses represent areas of research that will likely contribute to the complexion of the discipline in the future.

Geographic Area Hypothesis

The latitudinal gradient in which richness peaks in the tropics may be a consequence of the larger landmass of the tropics compared to other geographic zones. This simple idea had its genesis in the work of Terborgh (1973), with considerable development and refinement by Rosenzweig (1995) in subsequent years, during which the effects of productivity and zonal bleeding have been incorporated into a more comprehensive conceptual model. Nonetheless, the geographic area hypothesis has generated considerable controversy and contention (Rohde, 1997). The controversy does not surround whether an areal mechanism operates; it rather focuses on the degree to which variation in area is the dominant factor molding latitudinal gradients in richness.

Two features of the earth's geometry predispose the sizes of tropical regions to be greater than those of their higher latitude counterparts. First, the earth is essentially a sphere. The distance between longitudinal meridians at the equator is greater than that elsewhere on the globe, and intermeridian distance decreases in a regular fashion toward the poles. Second, northern and southern tropical zones are adjacent, whereas the northern and southern variants of other latitudinally defined zones are isolated from each other. Nonetheless, the positions, sizes, and configurations of the earth's continents will affect the proportion of land or water in tropical versus extratropical regions, and this has varied over geological time as a consequence of plate tectonics. In addition, the number and breadth of zones used to subdivide latitude will affect the perception of areal dominance associated with the tropics. For example, a tripartite division (torrid, temperate, and polar) reveals that the tropics rank second in area to north temperate regions at the global scale, with considerable variation in the proportional area represented by the tropics among continents (approximately 38%, 12%, 80%, 41%, and 0% of America, Eurasia, Africa, Australia, and Antarctica, respectively). In contrast, finer resolution of zones to tropical, subtropical, temperate, boreal, and tundra indicates the areal predominance of tropical lands globally.

Most important, the degree of environmental variation within the tropics is less than that in other geographic zones, at least with respect to incident solar radiation and temperature. Specifically, a band of 50° centered on the equator evinces no or little change in mean annual temperature with latitude (constant at approximately 27 °C), whereas mean annual temperature decreases thereafter by approximately 0.75 °C per degree latitude. Hence, regardless of the size of zonal subdivisions chosen to define tropical or extratropical regions, tropical landmasses are larger than any other landmasses with similar variation in temperature.

As a consequence of the areal extent and homogeneity of temperature and solar insolation in the tropics, speciation

rates there should be higher and extinction rates lower than in extratropical regions. Specifically, the larger area of the tropics allows its species to have larger ranges than do their extratropical counterparts. Larger ranges allow species to be represented by more populations or populations of larger size, both diminishing the likelihood of extinction resulting from accidental cause or from environmental perturbation. Simultaneously, larger areas are more likely to contain or experience geological events that produce geographic barriers that enhance the rate of allopathic speciation. The dynamic balance between the rates of speciation and extinction, therefore, yield higher equilibrium richness in the tropics than in extratropical areas (Figure 8).

Rosenzweig and colleagues marshal many lines of evidence in support of the geographic area hypothesis by citing two kinds of observations. First, larger biotic provinces, regardless of latitude, have more taxa than do their smaller counterparts (e.g., generic, familial, and ordinal richness of mammals increase with provincial area). Second, diversities from the same biome but from different continents or provinces differ as a function of their areal extent (e.g., rain forest vertebrates and plants as well as tropical freshwater fish increase in richness as their areal extent increases). Situations in which the general pattern does not occur usually include large but unproductive climatic zones with few species – effectively the richness-diminishing effects of low productivity may countermand the dominant role of area in these systems. In contrast, Rohde (1997) considers area not to be the dominant factor that affects high species richness in the tropics. He illustrates the point with Eurasian freshwater fishes, and shows that much smaller tropical regions have much greater species richness than do larger cold-temperate regions. Similarly, the expansive deep-sea biome with more or less constant temperature has far fewer species than its smaller tropical counterparts. Clearly, consensus is elusive concerning

the relative importance of area in affecting species richness compared to other mechanisms.

Because bats exhibit exceptionally strong latitudinal gradients of richness at multiple spatial scales in the New World, they are an appropriate biota with which to test the geographic area hypothesis (see Willig and Bloch, 2006). Importantly, ecogeographic zones of the New World (biome types and their constituent biogeographic provinces, *sensu* Udvardy, 1975) are not larger at tropical versus extratropical latitudes, and the spillover of tropical species into ecogeographic zones within extratropical regions generally does not diminish the association between richness and area. Nonetheless, the latitudinal gradient of species richness is strong and significant at both ecogeographic scales for all bats, as well as for the three most species-rich families (Molossidae, Phyllostomidae, and Vespertilionidae). Area does not drive the latitudinal gradient of bat species richness in the New World. In fact, area represents a source of noise rather than a dominant driver of the pattern.

Evolutionary Speed

After a broad and incisive review of the various mechanisms purported to cause latitudinal gradients in species richness, Rohde (1992) found them all to be lacking. Instead, he suggested that the gradient was a consequence of differential rates of speciation associated with an important latitudinal correlate, temperature, rather than being a product of equilibrium-based ecological processes that presupposed that local communities are saturated with species. His conceptual model is erected on the foundation of three premises. First, tropical environments support shorter generation times for many homeotherms and poikilotherms. Second, mutation rates increase as temperature increases and are highest in the tropics. Third, faster physiological processes occur at higher temperatures; this, coupled with the first two relationships, suggests an accelerated rate of fixation of favorable alleles in tropical populations. This effectively results in greater evolutionary time in the tropics for mechanisms of diversification to attain fruition.

The potential effect of evolutionary speed on latitudinal gradients of species richness has been evaluated for taxa representing terrestrial and aquatic ecosystems as well as vertebrate and invertebrate taxa. Many studies found support for increased diversification rates contributing to latitudinal gradients of species richness; however, evidence that the speed of molecular evolution is an important driver of those gradients is equivocal. For planktonic foraminiferans, temperature affects per individual speciation rates, contributing to the latitudinal gradient of species richness (Escarguel *et al.*, 2008). In contrast, there was no relationship (direct or indirect) between latitude and rates of molecular evolution in birds (Bromham and Cardillo, 2003). Rather than particular environmental conditions, rapid shifts between climatic regimes cause greater species richness for birds in the tropics (Kozak and Wiens, 2010), with sister species being more climatically divergent in the tropics and niche conservatism being the rule in temperate zones (Kozak and Wiens, 2007). The richness gradient for basal bird taxa is indistinguishable from that for all birds,

Figure 8 Graphical model illustrating the dynamic equilibrium between rates of speciation and extinction for tropical and extratropical latitudes. Modified from Rosenzweig ML (1995) *Species Diversity in Space and Time*. Cambridge, MA: Cambridge University Press.

whereas the richness gradient for derived taxa is much shallower (Hawkins *et al.*, 2006). This suggests that climatic dynamics through evolutionary time and effective evolutionary time, rather than evolutionary speed per se, may contribute to latitudinal gradients of species richness.

Rapoport–Rescue Hypothesis

As its name implies, this hypothesis is a hybrid of two mechanisms operating in tandem: the Rapoport effect and the rescue effect. A geographic pattern in which species range size decreases from high to low latitudes came to the forefront of the macroecological literature a few decades ago (Stevens, 1989), and has been termed Rapoport's rule after the Argentinian scientist who first discussed the pattern in the context of many other areographic principles. Stevens hypothesized that the latitudinal propensity for range size to decrease toward the tropics, when combined with differential movement of individuals from source to sink habitats (rescue or mass effect), can generate the latitudinal gradient of diversity.

Specifically, at any one locale in the temperate zone, an individual must be able to tolerate considerable intra-annual variation in climatic conditions; thus, species that occur in the temperate zone can attain a wide latitudinal distribution because of the broad tolerance of its constituent individuals to varying local conditions. In contrast, an individual in the tropics experiences little seasonal variation in climatic conditions; consequently, species comprising individuals that occur in tropical zones are predisposed to have narrower latitudinal distributions. This creates the Rapoport effect.

The rescue effect is a phenomenon whereby local extinction of a population, often in marginal or sink habitats, is prevented because of immigration of individuals from source or high-quality habitats. Because smaller ranges, which are differentially situated in the tropics as a consequence of the Rapoport effect, have greater perimeter to area ratios, they are predisposed to having greater rescue effect areas relative to range areas. This differentially inflates species richness in tropical areas, generating the latitudinal gradient of diversity.

The generality of Rapoport's rule, as well as the degree to which empirical patterns are generated by the hybrid mechanisms embodied in rescue and Rapoport effects, are controversial. The Rapoport effect has been documented for a diversity of taxa (mammals, reptiles, amphibians, fish, crayfish, amphipods, mollusks, and trees) in aquatic and terrestrial environments, and quickly became engrained as the explanation for species diversity gradients in a variety of ecology textbooks. Additional circumstantial evidence was derived from the observation that taxa, which do not show the general latitudinal gradient in richness, do not adhere to Rapoport's rule, suggesting that both patterns had a shared mechanistic basis (Stevens, 1989). Nonetheless, a growing body of evidence suggests that the Rapoport pattern is far from universal (Rohde *et al.*, 1993; Lyons and Willig, 1997). Moreover, re-analyses of data on marine mollusks that was used to corroborate the Rapoport effect (Stevens, 1989) failed to produce the same patterns in a subsequent study, even though the methods were the same in both studies (Roy *et al.*, 1994). In

addition, New World bats and marsupials (Lyons and Willig, 1997; Willig and Lyons, 1998), as well as nonmigratory marine teleosts from surface waters (Rohde *et al.*, 1993), each exhibit strong latitudinal gradients in diversity but do not adhere to Rapoport's rule. Hence, occurrences of latitudinal gradients in diversity do not have one-to-one correspondence with the existence of a Rapoport effect.

Simulation models provide added insight into the phenomenon of Rapoport's rule. The three commonly used methods (i.e., Stevens', midpoint, and most distal point) for assessing a Rapoport effect suffer from serious limitations. Stevens' method is problematic because of a lack of independence associated with counting the same species multiple times in the same analysis (Rohde *et al.*, 1993). Midpoint and most distal point methods suffer from severe mathematical biases – the bounded nature of continents or oceans predisposes correlations between range size and latitude even when ranges are distributed stochastically with respect to latitude (Colwell and Hurtt, 1994; Lyons and Willig, 1997). Finally, a comprehensive set of simulation models (Taylor and Games, 1999) suggests that the Rapoport effect causes a latitudinal pattern in species richness, but the gradient is opposite of the pervasive pattern found in nature in that species richness increases with increasing latitude. Moreover, incorporation of a rescue effect into the model so that it reflects the Rapoport–rescue mechanism still fails to rescue the hypothesis; the predicted pattern remains a decrease in richness toward the tropics. Only the incorporation of competitive effects either to the simulation model based on the Rapoport effect alone or to the combined Rapoport–rescue mechanism produces latitudinal gradients that are consistent with real-world patterns, and in both scenarios, communities must be saturated at equilibrium compositions.

Geometric Constraints Hypothesis

One of the newer ideas to explain latitudinal gradients in biodiversity is the geometric constraints hypothesis (Colwell and Hurtt, 1994; Willig and Lyons, 1998). Geographic constraints may affect patterns of species distribution within a domain, creating modal patterns of biodiversity in the middle of the domain (i.e., the mid-domain effect). Within the context of latitudinal gradients, this hypothesis would consider peak biodiversity in the tropics to be a consequence of the bounded nature of terrestrial and aquatic habitats. Indeed, both simulation (Colwell and Hurtt, 1994) and analytical (Willig and Lyons, 1998) null models suggest that species richness of a biota should increase toward the center of a shared geographic domain in a quasiparabolic or parabolic fashion as a consequence of the random placement of species ranges within the domain. Other mechanisms proposed to account for latitudinal gradients only suggest qualitative increases in richness with decreasing latitude. In contrast, geometric constraint models make quantitative predictions concerning the form of the latitudinal gradient so that expected values for richness occur for each latitude and can be compared to empirical data.

Multiple null models that differ in the number and type of constraints have been developed to evaluate this geometric

Figure 9 Graphical representation (parabola) of the gradient of species richness that arises from the random placement of species ranges within the latitudinal bounds of the New World, scaled from 0 in the south to 1 in the north. (Modified from Willig MR and Lyons SK (1998) An analytical model of latitudinal gradients of species richness with an empirical test for marsupials and bats in the New World. *Oikos* 81: 93–98.) The number of species at any latitude is determined by its proportional distance (p) from the southern boundary and is given by $(2p - 2p^2)S$. The vertical lines labeled A and B represent the latitudinal extents of bats and marsupials, respectively.

hypothesis. The fully neutral model (Colwell and Hurtt, 1994; Willig and Lyons, 1998) defines the expected pattern of species richness while ignoring potential effects of extant environmental gradients, as well as the history of the domain, on species' ranges sizes. Other null models apply additional constraints on randomizations, such as requiring the range size frequency distribution (RSFD) or the distribution of midpoints in the domain to equal the empirical distribution. For the fully neutral model, the number of species at any point within the domain (Sp) is related only to the proportional distance of that point from the boundary (p) and the number of species in the species pool (S), and is given by $Sp = 2p(1 - p)S$. This model (Figure 9) is an incarnation of both the two-hit broken stick model of MacArthur and the binomial distribution. In essence, if the latitudinal domain of a biota is rescaled to range from 0 in the south to 1 in the north, then the likelihood of a species range overlapping any point P that is exactly p from the southern terminus (and hence $1 - p$ from the northern terminus) of the domain is

$$Pr(P) = 1 - p^2 - (1 - p)^2 = 2p - 2p^2$$

where p^2 is the proportion of species whose northern and southern boundaries lie to the south of P , and $(1 - p)^2$ is the proportion of species whose northern and southern boundaries lie to the north of P . The functional form of the distribution of $Pr(P) = 2p - 2p^2$ is a parabola that peaks at 0.5, and as a consequence, the average range size of species in the biota is half the extent of the domain (0.5).

Distributions of range midpoints and RSFDs are the collective product of responses to environmental gradients, biotic interactions, and historical processes (Hawkins *et al.*, 2005). Consequently, null models that use such constraints incorporate empirical responses to environmental variation and historical processes into “null” patterns that are produced by

Figure 10 Comparison of the empirical latitudinal gradient of species richness (dots) with the predicted values (outer lines represent 95% confidence bands, and inner line represents predicted value) generated by a null model constrained only by the distributional bounds of the fauna for bats (a) and marsupials (b) in the New World. Modified from Willig MR and Lyons SK (1998) An analytical model of latitudinal gradients of species richness with an empirical test for marsupials and bats in the New World. *Oikos* 81: 93–98.

the randomization. Constrained models produce a quasi-parabolic curve that becomes increasingly flattened as mean range size diverges from 0.5 (the mean value in the fully neutral model). If the mean range size is >0.5 , species richness in the middle of the domain will be higher and the peak broader than that for a comparable fully neutral model. Alternatively, a RSFD with a mean range size <0.5 will have a richness peak that is lower and broader than that of a RSFD with a mean range size of 0.5 (Colwell *et al.*, 2004).

Considerable debate exists about the application, utility, and interpretation of geometric constraint null models with respect to empirical data (e.g., Colwell *et al.*, 2004, 2005; Zapata *et al.*, 2003, 2005; Hawkins *et al.*, 2005). Importantly, these null models provide baseline expectations for gradients of species

richness in domains in the absence of ecological and evolutionary mechanisms, for the fully neutral model, or given particular distributions of midpoints or species range sizes, for models that incorporate additional biological constraints. Consequently, deviations from null model predictions should be the focus of interpretation for empirical applications of geometric constraint models. For example, a geometrically constrained null model was able to account for 69–95% of the latitudinal variation in species richness for New World bats and marsupials (Figure 10; Willig and Lyons, 1998), indicating that latitudinal richness gradients for these taxa approximate null expectations for models that incorporate empirical RSFD, and the ecological and evolutionary mechanisms they represent. Nonetheless, systematic deviations from the null distribution were observed for each taxon, and these deviations represent important foci for further inquiry into mechanisms that mold latitudinal gradients of biodiversity.

Geometric constraint models make predictions (i.e., estimates based on null models) for multiple aspects of latitudinal richness gradients, including the precise shape of the symmetrical curve, as well as the size and location of the single peak in species richness. A comprehensive analysis of geometric constraints on gradients associated with latitude, longitude, ocean depth, or elevation found poor congruence between empirical patterns and those generated by geometric constraint models (Zapata *et al.*, 2003). Nonetheless, this exercise is valuable as systematic deviations from null model predictions can generate more specific hypotheses about mechanisms that shape gradients of species richness. In addition to one-dimensional models, two-dimensional models based on latitudinal and longitudinal constraints have been used to more fully evaluate the potential for geographic constraints to mold gradients of richness. Two-dimensional models fit empirical data more poorly than do one-dimensional models associated with latitude (Zapata *et al.*, 2003; Kerr *et al.*, 2006). Geometric constraints provide the greatest insights when the axis of constraint that defines the domain is associated with important environmental gradients, as is the

case for latitude, elevation, and ocean depth, when deviations from predictions suggest possible causal mechanisms.

A geometric constraint approach can enhance the understanding about the relative contributions of evolutionary, environmental, and historical factors to latitudinal gradients of biodiversity. Random processes may predispose particular biotas to produce gradients with peaks in richness at mid-latitudes. The challenge for large-scale ecology is to understand the mechanisms that result in deviations from such null models, create peaks in biodiversity, and define the form of the biodiversity–latitude relationship.

Assessment and Synthesis

The ontogeny of theory can be viewed from a variety of perspectives that deal with the detection of patterns, the linkage of patterns to particular mechanisms, and ultimately the integration of those constructs to other theories in the discipline (Scheiner and Willig, 2011). The theory of latitudinal gradients of biodiversity has matured considerably since the first edition of this book. The general patterns of latitudinal increase in species richness remain well documented from an empirical perspective. Recent meta-analyses on more than 500 published latitudinal gradients (Hillebrand, 2004) reaffirmed the generality of the established pattern based on considerations of effect sizes (slopes and coefficients of determination). This analysis established that patterns were stronger and steeper for assemblages (large grains) than for communities or samples at the local level (small grains), but that the latitudinal extent of the domain did not affect the nature of the gradient. The relationships in marine and terrestrial environs were stronger and steeper than those in freshwater environs, and the gradients were different among continents but not between northern and southern hemispheres. Body mass, trophic level, and thermoregulatory capacity of the targeted biota had an effect on nature of gradients as well.

Figure 11 Conceptual model (modified from Willig MR, Kaufman DM, and Stevens RD (2003) Latitudinal gradients of biodiversity: Pattern, process, scale, and synthesis. *Annual Review of Ecology Evolution and Systematics* 34: 273–309) indicating likely mechanisms whereby latitude may affect alpha- (α), beta- (β), or gamma- (γ) components of biodiversity. Latitude is a surrogate for correlated spatial or environmental characteristics (e.g., energy, temperature, and midpoint distance in the domain, area) with which it covaries. These spatial and environmental covariates figure centrally in dominant hypotheses associated with the latitudinal gradient in species richness.

The manner in which particular mechanisms could affect patterns of species richness has become clearer, and elements of the theory have been used to understand other gradients of biodiversity, such as those related to elevation, depth, or productivity. Moreover, latitudinal patterns of species richness are being integrated with other broad-scale patterns concerning the dominance and turnover of species, as well as to latitudinal patterns of range size and abundance, representing a significant advancement in understanding and integration. The past decade has seen renewed interest in evolutionary and historical mechanisms in addition to those of a more ecological nature.

Although few of the hypotheses postulated to affect the latitudinal gradient in species richness have been eliminated in a conclusive manner, research concerning many of the mechanisms appears more likely to advance theory in the near future. Indeed, recent synthetic works have focused on them to a great extent. Understanding the contexts and degrees to which area, climatic variability or stress, geographic constraints, productivity, temperature, and their interactions mold the latitudinal gradient in diversity remains a challenge for scientists to synthetically address in the coming decade. For example, the synthesis by Willig *et al.* (2003) provides a conceptual model (Figure 11) of how latitude as a surrogate for considerations of energy, temperature, geometric constraints, and area (hypothetical mechanisms for the latitudinal gradient) differentially affects species richness at different focal scales as well as the association between them.

In contrast to the situation regarding species richness, the state of theory regarding latitudinal gradients of other aspects of the taxonomic dimension (e.g., evenness, diversity, and dominance) or of other dimensions of biodiversity (e.g., functional and phylogenetic) is in its infancy. General latitudinal patterns for aspects of biodiversity other than species richness have not been well established. Moreover, the mechanistic bases of these more complex gradients have been explored only in a rudimentary manner. Nonetheless, it is clear in the limited number of cases where they have been explored that latitudinal gradients in nontaxonomic dimensions of biodiversity are not wholly explicable by gradients in species richness and that historical factors may play a significantly important role.

Glossary

Circannual rhythms Endogenous, or internal, rhythmic cycles of one year in duration that govern the onset and cessation of migratory behaviors.

Compass orientation Navigation in a particular direction without reference to landmarks or sites of origin or destination. Migrants are known to use compass information from magnetic fields, chemical gradients, and visual features such as the stars, sun, and planes of light polarization.

Diadromy Migrations that take individuals between fresh and salt-water habitats, a common phenomenon for many migratory fish species.

Partial migration The case where intrapopulation variation in migratory behavior leads some individuals to migrate while others within the same population may only migrate locally or remain sedentary.

Zugunruhe Restlessness exhibited by some migratory species, especially birds, if not allowed to migrate during their usual migratory period. It reflects an underlying physiological transition to a migratory state.

Migration describes the movement of individuals between spatially separate ecological communities, typically on a seasonal or annual schedule. Several characteristics of migrations distinguish them from other forms of animal ranging behavior, including more persistent movements, of greater duration, that follow a more direct path with fewer turnings. Furthermore, migrants do not respond to resources along their path, but show a heightened response to the same resources near the migratory journey's end. This latter feature distinguishes migrations from typical foraging and dispersal movements. Behavioral specializations may include specific activity patterns particular to departure and arrival, and unique patterns of energy allocation to support long-distance movements. The ecological consequences of migration are that they take a species from one community of organisms to another and they partition life histories so that specific phases or events occur in different ecological communities. Given these specific characteristics, human alterations to the landscape and changes to global climate are likely to have dramatic consequences on the nature of migration as well as the migratory species themselves and the communities and habitats they connect.

Introduction

Migrations capture the human imagination like few other animal behaviors. The single-minded struggle of the salmon fighting its way upstream, the barely visible formation of geese piercing the sky overhead, and the thundering line of wildebeest snaking across the open savanna – all speak of ancient rhythms that drive life on our planet. The often great distances moved and the large numbers of individuals involved make

animal migrations a conspicuous and essential aspect of many regions' biodiversities. Animals migrate for many reasons but in general do so to avoid temporarily unfavorable conditions or to locate particularly favorable areas that can meet specific biological needs, such as reproduction. However, it is somewhat ironic that migrations might actually increase a species' risk rather than reduce it. Protecting migratory species requires preservation not only of their final destinations but also their migratory routes and stopover points as well. In effect, migration inextricably links the fates of biotas across the length and breadth of the globe. No natural phenomenon makes the point better that biodiversity on local and global scales shares the same actors and the same processes that drive them. In this article we explore the nature, scope, and patterning of animal migrations as a prelude to discussing how human-caused changes in the environment are likely to impact migratory species. We not only address direct effects on migratory species behavior, ecology, population dynamics, and evolutionary potential, but we also consider indirect impacts on the ecological communities and regional biodiversities that disruption of migrations can produce.

What is Migration?

Definitions of "migration" abound in the scientific literature, many of which capture the nature of the behavior for specific taxa but fail to generalize across taxa. Commonly cited elements include long distances traveled and movements from one place to another, then back again. But what is "long"? Dark-eyed juncos (*Junco hyemalis*) and Blackburnian warblers (*Dendroica fusca*) are both small passerine birds that migrate with the seasons; both breed at higher latitudes in

northeastern Canada (among other sites) yet juncos may migrate only a few hundred kilometers to their overwintering range while Blackburnian warblers fly several thousand kilometers to overwinter in the Andean forests of Ecuador. The lengths of these respective trips differ by an order of magnitude, yet in examining the ecology and behavior of each species, we might well consider both to constitute migrations. For example, both involve moving between distinct ecological communities on a consistently timed, seasonal basis. Similarly, “typical” migrants, like most birds, travel the same circuit each year. Others, however, may only complete a single circuit in their lifetime (e.g., salmon) or only part of a circuit before they die, such as insects in which successive generations continue the journey their predecessors began. Should we exclude such species from the “migratory” category despite other aspects of behavior, physiology, and life history held in common with typical migrants?

From a biodiversity perspective, migration drives a species’ life history and pattern of resource use, and it ties together ecological communities in different regions. Thus, defining migration in ecological terms of a species’ use of space over time is imperative to understanding its functional impacts on biodiversity. However, one also needs to ask, does biodiversity refer to just the specific organisms found within a region, or does it encompass the specialized behaviors such organisms display? Ecological consequences aside, are sedentary populations of Canada geese interchangeable with migratory ones when summing up a region’s biodiversity? If migratory and nonmigratory races or subpopulations – whether genetically or phenotypically different – each represent unique components of biodiversity, then for distinguishing them we must also define “migration” in terms of the behavioral mechanisms.

The combined ecological and behavioral dimensions of migration have plagued attempts to come up with a single definition suitable from both perspectives. Ecological definitions have included “the act of moving from one spatial unit to another” by Baker (1978) and “the persisting change that is left over when all other, minor excursions are removed” (Taylor and Taylor, 1983). Both capture the essential idea of migrations extending the ecological space used by individuals, although ambiguity over what constitutes a spatial unit or minor excursion renders each too imprecise to be of much use in distinguishing migratory from nonmigratory species.

Dingle (1996) has proposed a definition of migration that emphasizes the differences between migrations and other forms of animal movement. He uses clear behavioral terms to distinguish migrants from nonmigrants, yet he uses each species as its own reference for differentiating movements with different ecological consequences. Generally put, nonmigratory (ranging) movements are driven by the immediate need to acquire or safeguard resources, and they cease when suitable resources are encountered or are adequately defended. The length and timing of foraging and territorial defense movements will vary daily, or on even shorter time scales, depending on the frequency of encountering resources or potential threats. Commuting daily between refugia and feeding locations, such as the diel movements of zooplankton and other aquatic animals, is similarly directed by resources

and is responsive to their location and abundance. Even dispersal to establish a new home range or to leave a natal group usually ceases as soon as a suitable new home range is found. In contrast, once they set out, migrants will ignore many of the resources they encounter, or use them briefly to refuel, and only become responsive again to resource abundance and quality after all or a critical part of their journey has been completed. Migratory movements thus entail specific changes in behavior and physiology that distinguish them from nonmigratory movements, even those that are circular in nature. Defining migrations relative to a species’ other forms of movement results in a more generally applicable definition and one that encompasses the diversity of the migratory behaviors animals display.

Specifically, five mechanistic attributes distinguish migratory behavior (Dingle, 1996). The movements are: (1) more persistent and of greater duration than ranging movements and (2) follow a more direct path with fewer turnings. There is (3) an initial suppression of responses to resource-derived stimuli, but often a heightened response to such stimuli near the migratory journey’s end. Migrants may also have (4) specific activity patterns particular to departure and arrival and (5) unique patterns of energy allocation to support long-distance movements. Of course, not all migrants will show all five characteristics, but as a group these traits circumscribe the suite of distinct and specialized behaviors entailed in migration. To these behavioral attributes we add two functional hallmarks of migrations: (6) they take a species from one community of organisms to another; and (7) they partition life histories so that specific phases or events occur in different ecological communities.

Two common uses of the term “migration” will not be considered in this article: (1) migration in the paleontological sense of species shifting their historical distributions with climate change or geological events and (2) migration as geneticists use the term to refer to gene flow between populations.

The Evolution of Migration

To move from one area to another and back, organisms must evolve the ability to detect and react to directional cues in the environment. Typically these can range from local cues associated with monitoring and tracking changes in essential resources, to more global cues associated with magnetic, celestial, or odor fields. But evolving these capabilities are not without costs; cue detection is likely to be error prone and to lead to lowering of vigilance levels. Since selection will maximize the difference between benefits and costs associated with enhanced detection ability, an intermediate or modest level of gradient detection ability should be evolved. Moreover, recent models show that because of the costs associated with gradient detection, only a few individuals should evolve gradient detecting abilities in social species (Guttal and Couzin, 2011). Most individuals will be selected to parasitize the gradient detecting abilities of a few leaders. Just as in many other social contexts where some individuals produce resources but others scrounge (Barnard and Sibly, 1981), or some invest in establishing elaborate and costly mating

territories while others hover nearby and surreptitiously steal matings from approaching females (Rubenstein, 1981).

Just as polymorphisms in the detection of directional cues can be maintained in populations, polymorphisms in the synchrony of migration and the fraction of individuals within populations to migrate can evolve. Maintenance of such polymorphisms often occurs in annually reproducing species when subpopulations share a breeding ground and overwinter apart, or share an overwintering ground and breed apart. Such dual strategies evolve when the effects of crowding on survival and reproduction can be reduced by subdividing and separating the population during one of the seasons (Griswold *et al.*, 2010). But partial migration can also evolve when some fraction of the population skips breeding and remains in the nonbreeding habitat while those engaging in breeding migrate to the breeding grounds (Shaw and Levin, 2011). In this case, dual strategies evolve because of tradeoffs in current versus future reproduction. In general, for some in the population postponing breeding and avoiding the costs of migration is favored when mortality associated with migrating, or the benefit of delaying to increase body to enhance future breeding, or the probability of impending harsh conditions will diminish current reproduction is high for a subset of the population. Thus, as environmental conditions become more severe it is likely that collective migratory synchrony will decline and more populations will exhibit dual strategies.

Migratory Patterns: A Taxonomic Survey

The diversity of migratory behavior in animals overwhelms attempts to neatly summarize its character and function. Generally, animals migrate to escape unfavorable conditions or to exploit favorable ones, yet defining “favorable” or “unfavorable” is often specific to the taxon examined and the life-history function at hand. Polar and cold temperate habitats tend to have more migrant species than tropical ones because they vary so strongly in productivity and habitability, although this tendency differs widely among the major taxonomic groups. Migration distance and duration similarly vary to a great degree, even within groups of species that migrate for the same reason. Differences in physiology account in part for this variability, since larger body sizes can store relatively more energy to fuel longer trips and lower the weight specific cost of transport while certain forms of locomotion, such as flying or swimming, are more efficient than others. In addition to physiology, physical forces such as winds and currents act in concert with habitat topography to further shape the migratory route and schedule. Biogeographic history may even play a role in these features of migration since routes may be hard-wired genetically and slow to adapt, or learned and dependent on knowledge within lineages. Indeed, migrations present a truly fascinating mix of evolutionary puzzles in behavior, ecology, physiology, and biogeography (see Dingle, 1996, for an excellent introduction to these). The broad surveys that follow provide an overview of migration prevalence, function, and character for the major taxa with specific emphasis on the biodiversity of migrants per taxonomic group and region.

Birds

Birds epitomize the act of migration for many people. Whether one lives in the temperate zone or tropics, New World or Old, Southern or Northern Hemisphere, migratory species constitute a significant and conspicuous fraction of the avifauna. At the most northern and southern latitudes, close to 100% of bird species migrate out of the region for a part of the year. For example, 135 species breed in the arctic zone, yet all migrate south to spend most of their year elsewhere (Johnson and Herter, 1990). In more temperate regions, a majority of species, and nearly all insectivores, migrate to more tropical latitudes after breeding (Karr, 1980). Approximately 200 species migrate from North America to the West Indies, Central, and South America each year, while many more make shorter distance migrations into the southern US and Mexico. In Europe, 177 species, or 40% of the region’s avifauna, migrate from temperate breeding grounds to overwinter in Africa; 104 species from Western, Central, and Eastern Asia join them there. Moreau (1972) has estimated that 5 billion individuals make this migratory journey south to Africa alone; the comparable number for the entire globe is surely several times this. Seasonal fluctuations in temperature ultimately drive food production cycles at higher latitudes, setting the schedule for migratory movements, but in tropical climates distinct wet and dry seasons may function in an identical manner. Substantial numbers of birds follow regular migratory routes that track resources such as fruiting or flowering trees, seeding grasses, or invertebrate flushes brought about by rains. Indeed, this form of short-distance movement may be the most common type of migration in birds. For example, out of 1450 breeding species in Africa, 532 species have been classified as intra-African migrants (Curry-Lindahl, 1981).

Bird migration is clearly a ubiquitous feature of our planet’s biodiversity, yet migrant species are not distributed equally around the globe. Particularly, birds that migrate in excess of 1000 km – moderate- and long-distance migrants (Berthold, 1993) – are more prevalent as breeders in the northern hemisphere. This is largely due to the much greater land area at higher latitudes in the Northern than in the Southern Hemisphere. For example, only 20 species among the hundreds that breed in the temperate regions of southern Africa migrate as far north as the equator, while a much larger number and proportion of Palearctic species overwinter in the same equatorial region (noted earlier). Similarly, only 8% of the nearly 600 species breeding in Australia and Tasmania migrate in and out of the temperate zone (Faaborg, 1988). In the New World, 31 species of shorebird (e.g., plovers, sandpipers, and curlews) breed at higher latitudes in the Northern Hemisphere and migrate thousands of kilometers to spend their nonbreeding seasons in the Southern Hemisphere, yet not a single shorebird species that breeds in the south even migrates as far north as the equator during its nonbreeding season (Hayman *et al.*, 1986). Although the actual bases for these fascinating patterns remain relatively unexplored, they suggest a greater sensitivity of northern avifaunas to factors that threaten moderate- and long-distance migrants off their breeding grounds.

Long-distance migrants accomplish truly stunning feats. Blackpoll warblers (*Dendroica striata*), weighing only 10–20 g,

embark from Cape Cod on a nonstop, 86 h, 3500 km flight 2000 m above the waves of the Atlantic to the northeastern coast of South America (Baird, 1999; Williams and Williams, 1978). Tundra-breeding shorebirds such as the Pacific golden plover (*Pluvialis fulva*) make nonstop 5000–7000 km journeys to wintering grounds in the South Pacific (Johnson and McFarlane, 1967). Arctic terns (*Sterna paradisaea*) have the longest migration of any bird, and perhaps any animal, traveling an annual circuit that can exceed 40,000 km (Alerstam, 1985). They breed in the boreal summer along the northern edges of the Old and New World continents, then migrate along the western edges of North America, South America, Europe, and Africa to feed in the rich waters off Antarctica's pack ice during the austral summer. Almost 8 months of each year are spent in transit between these two endpoints.

The Arctic tern's migratory journey seems extraordinary but it typifies why many birds migrate (Gauthreaux, 1982). In doing so, they exploit highly seasonal flushes of food resources, especially to meet the increased demands of breeding. High variability in food supply at higher latitudes, especially in insects and other invertebrates, makes it difficult for species to reside permanently in the habitat. However, the very predictable nature of these fluctuations allows mobile species to rely on them for part of their annual cycle. The absence of resident competitors may make these ephemeral resources even more abundant and accessible to migrants. Thus, the typical migratory movement for birds involves making an annual round trip between seasonally resource-rich breeding sites and nonbreeding areas where resource abundance may be lower but less variable over time.

Seasonal resource variability explains why many birds migrate, but what determines how far they go and where their final destinations lie? Proximal determinants of migration distance and route include weather patterns, history, the distribution of resources along the way, and the character of the landscape (Lövei, 1989; Kerlinger and Moore, 1989; Williams and Williams, 1978; Dingle, 1996; Berthold, 1993). The north–south orientation of mountain ranges in North, Central, and South America tend to funnel migrants along corridors also running north–south, whereas Eurasia mountain ranges run east–west, forcing many Palearctic migrants to make large westerly movements before they are able to fly south. The importance of trade winds or winds generated by weather fronts to migratory journeys can be seen often in the very different routes followed when moving north versus south (e.g., Arctic tern study by Alerstam, 1985). The migratory path of the white-rumped sandpiper (*Calidris fuscicollis*) extends the length of the Western Hemisphere and appears carefully choreographed to coincide with seasonal pulses of invertebrate prey along the route (Harrington, 1999). History too seems to shape migratory paths and destinations as suggested by the very indirect route (via the eastern Mediterranean) taken by red-backed shrikes (*Lanius collurio*) migrating from the Iberian Peninsula to their nonbreeding range in Central Africa (Berthold, 1993).

Habitat suitability is a more ultimate determinant of migration distance and destination. Species with very specific habitat requirements may have limited options for suitable nonbreeding areas. For example, the upland sandpiper (*Bartramia longicauda*) breeds in North American grasslands

and must travel 10,000 km to overwinter in the pampas of Argentina – the only similar Southern Hemisphere grassland habitat in the New World. Many tundra-breeding shorebirds migrate to the southern coastlines of South America, Africa, Southeast Asia, and Australia where extensive intertidal mudflats and rocky beaches provide abundant invertebrate prey. Most neotropical migrants – the warblers, flycatchers, vireos, swifts, hummingbirds, swallows, tanager, orioles, and raptors – migrate more moderate distances to forest and scrub habitats in Central America, the West Indies, and northern South America. In addition to the general structure of the habitat, competition with resident forest species and other migrants certainly influences where migrants settle during their nonbreeding seasons (Terborgh, 1989).

Often the question of how far migrants move depends on which population one examines. Many migratory birds conduct “partial” migrations where some individuals migrate while others remain as year-round residents on the breeding grounds or move only short distances (e.g., European blackbird, *Turdus merula*, Berthold, 1993). Different age and sex classes may pursue different migratory strategies, as in the dark-eyed junco of the eastern US (Ketterson and Nolan, 1983). Alternatively, all individuals may migrate but different populations travel different distances. A common pattern in this case is for higher-latitude breeding populations to migrate the longest distances, “leap-frogging” beyond the migratory movements of lower-latitude populations (e.g., fox sparrow, *Passerella iliaca*, Wetmore, 1926). Some sanderling (*Calidris alba*) populations migrate only a short distance from their tundra breeding grounds to overwinter in the northwestern US while others travel 7500 km to nonbreeding areas in Chile. Apparently, the much greater energetic and exposure costs of migrating to South America are offset by much richer food resources and a more hospitable climate, so that the payoffs for each strategy are equivalent, and both short- and long-distance migrants persist (Myers *et al.*, 1985).

The presence of both migratory and nonmigratory strategies in the same species underlines the opportunistic and flexible nature of bird migration. As environmental changes occur or as a species expands its range, migratory behavior can often adapt to fit the new circumstances. The European starling (*Sturnus vulgaris*) is a widespread, permanent resident of Britain today, yet in the eighteenth century starlings regularly migrated out of Britain to overwinter in warmer regions of Europe (Alexander and Lack, 1944). Long-term climate change has presumably made Britain a more hospitable place for starlings to spend their winters. Conversely, several year-round resident species in Europe have extended their breeding ranges north over the past century. These more northerly populations have developed full migrations to southern Europe for overwintering. Migrants may also establish nonmigratory populations along traditional migratory routes as resources become more abundant or habitats are altered, for example, the barn swallow (*Hirundo rustica*) in Argentina (Martinez, 1983) and the Canada goose (*Branta canadensis*) in eastern North America. With industrial parks in North America supporting extensive expanses of grassy lawns some Canada geese cannot only forage sufficiently well at temperate latitudes during the winter, but high levels of vegetative production during the spring and summer enable them to stay and breed.

A fascinating form of bird migration not related directly to food abundance is molt migration. It is particularly common among waterfowl that molt all their flight feathers simultaneously and thereby lose the ability to fly. To escape predation, they may migrate to coastal areas, large lakes, or far offshore until their new feathers have grown in.

Mammals

Small (<5 kg), nonvolant mammals represent a large fraction of our planet's mammalian biodiversity – rodents alone account for 40% of all mammal species – yet very few species are known to migrate. Rather than leave highly seasonal habitats when resource abundances decline, many small mammals hibernate or reduce activity levels and wait for conditions to improve. Species known to migrate include lemmings in the arctic tundra (Stenseth, 1983) and a variety of rats, mice, and shrews living on the Kafue River flats of Zambia (Sheppe, 1972). In both cases, these small mammals move several kilometers to escape flooding conditions as snow melts (lemmings) or rivers flood (Kafue mammals).

Migration occurs more commonly among a second, highly diverse mammal group, the bats (25% of all mammals). The ability to fly and travel large distances more efficiently than via terrestrial forms of locomotion must account in large part for this difference between bats and other small mammals. Fruit-eating bats in West Africa migrate 1500 km annually, following the movement of rains and the consequent pattern of fruit abundance (Thomas, 1983). As in birds, different sex and age classes may migrate different distances; juveniles migrate further, perhaps trading-off reproduction for more abundant food and greater survivorship. Similar migrations tracking fruit, nectar, and insect abundances have also been found in Australia and the New World tropics (Fenton and Thomas, 1985; Richards, 1995).

Insectivorous bats breeding in the temperate regions of North America and Europe commonly migrate, showing two distinct patterns of movement (Griffin, 1970; Nowak, 1994). Like many birds in these regions, species such as the Mexican free-tailed bat (*Tadarida brasiliensis*) and the hoary bat (*Lasiurus cinereus*) travel a maximum of 800–1700 km south to overwinter in warmer sites where their insect food can still be found. These individuals do not hibernate, but other individuals of the same species may make only part of the southward journey to hibernate at sites along the migratory route. The second migratory pattern involves movements of shorter distances (10–200 km), and more variable orientation, from summer ranges to particular winter hibernation roosts. For example, as Griffin discovered, the little brown myotis (*Myotis lucifugus*) hibernates in a few selective caves and mine tunnels in northern New England, yet migrates usually less than 100 km back to summer ranges both north and south of these wintering sites (Griffin, 1970). Seasonality determines the timing of migration in these species but the very specific requirements of hibernation, such as temperature stability, humidity, and protection from predators, drive migration distance and direction. It is not uncommon for 75–95% of the population in a large geographical area, or even an entire species, to migrate and hibernate in only a few caves (Pierson, 1998). Both migratory patterns are particularly common

among species that roost in trees during the summer, presumably because trees make very poor, exposed winter hibernation sites.

Among terrestrial mammals, migrations are most common, and most spectacular, in the ungulates, or hoofed mammals. In the Serengeti ecosystem of Kenya and Tanzania, more than 1 million wildebeest (*Connochaetes taurinus*) and several hundred thousand plains zebra (*Equus burchelli*) and Thomson's gazelle (*Gazella thomsonii*) migrate seasonally along a several-hundred-kilometer annual circuit. A spatially varying seasonal rainfall pattern, and the consequent growth in grass that it generates – the primary food of all three species – determines the migration's timing and route (Maddock, 1979), although drinking water availability and salinity may also play important roles (Wolanski *et al.*, 1999). Plains zebra and wildebeest populations elsewhere in Africa make similar migrations between wet and dry season grazing areas, but in smaller numbers. These species are not obligatory migrants, however, since resident, nonmigratory individuals can be found in most populations. Other ungulate migrations driven partly by seasonal food availability include the movements of caribou and reindeer (*Rangifer tarandus*) in the Holarctic region from tundra in the summer to taiga during winter (McCullough, 1985). The more wooded taiga also provides greater protection from harsh winter conditions; eastern North American populations of "woodland" caribou do not migrate at all.

Ungulates in temperate regions often migrate altitudinally with the seasons, moving to lower altitudes in winter to avoid harsh weather, low food abundance, and low food accessibility due to deep snow (McCullough, 1985). Such species include bighorn sheep (*Ovis canadensis*), elk (*Cervus elaphus*), mule deer (*Odocoileus hemionus*), and feral horses (*Equus caballus*) in the Nearctic and chamois (*Rupicapra rupicapra*) in the Palearctic. Migratory distances in these species are usually short. An interesting exception is the mule deer, where each individual or family has a definite summer and winter range yet the migratory route is often not the most direct link between them. Individuals have been observed to travel 150 km in straight-line distance, crossing six mountain ranges in a winding route to do so (Gruell and Papez, 1963). Tradition appears to have a tremendous effect on defining seasonal ranges and migratory routes in this species.

For marine mammals, annual migrations are the rule rather than the exception (Bowen and Siniff, 1999). The baleen whales, or mysticetes, migrate the longest distances, some moving thousands of kilometers from tropical to polar waters and then back again each year. Northern and Southern Hemisphere populations both migrate in this way, but their opposite schedules prevent overlap in the tropics. Food availability and quality at higher latitudes drive the timing of these movements. During the polar summer, long day lengths lead to phytoplankton blooms which, in turn, generate huge abundances of the zooplankton, such as krill, that baleen whales specialize on when feeding. The lipid content of krill and small fish prey, or energy per mouthful from the whale's perspective, also rises during the summer months (Mårtensson *et al.*, 1996). Indeed, polar waters provide such an amazingly rich food source that many species forego feeding the rest of the year, consuming enough during a 3-month summer binge

to not only maintain themselves for the remaining 9 months but also to complete a hemispheric round-trip and breed. In species such as the fin whale (*Balaenoptera physalus*) both mate and give birth 11 months later in warm, low latitude waters (Boyd *et al.*, 1999). Lactation lasts for 6–7 months and the calf is weaned on the summer feeding grounds; fat reserves for lactation just after birth may constitute 50–75% of a female's body mass. Lower thermoregulatory costs in warm water presumably allow the binge-migrate-and-fast strategies of baleen whales to be successful, especially since warm, tropical waters may also provide a thermal environment more conducive to calf growth.

Odontocetes, or toothed whales such as dolphins, pilot whales and beaked whales, may show regular seasonal movements between breeding and nonbreeding grounds, but long-distance migrations rarely occur (Bowen and Siniff, 1999). Most toothed whales feed on single food items like fish and squid and, as a consequence, must feed every day to maintain themselves. Many have large feeding ranges through which they travel 20–60 km per day (Wells *et al.*, 1999). Short-distance migrations typically occur when food abundance in an area changes seasonally, such as when fish schools move off-shore or concentrate in river mouths. Some Arctic odontocetes, such as the narwhal (*Monodon monoceros*) and beluga (*Delphinapterus leucas*), migrate short distances seasonally as the polar pack ice retreats and opens up calving grounds in warmer-water estuaries. When the ice returns, they move back with its advancing edge to deeper, ice-free waters. Only the sperm whale – the largest odontocete – migrates distances comparable to those seen in the baleen whales. Adult males move two- to three-times the distances of females, reaching richer feeding areas at higher latitudes in order to achieve and maintain their much larger body sizes (Best, 1979).

Among pinnipeds, 44% of phocid (true or hair seals) species migrate seasonally while only 14% of otariids (fur seals, sea lions) do so (Bowen and Siniff, 1999). This difference may arise from the phocid's greater reliance on seasonally changing pack ice, rather than solid land, as a substrate for giving birth, raising young, and molting. For example, harp (*Phoca groenlandica*) and hooded seals (*Cystophora cristata*) whelp on pack ice in March near Newfoundland, among other sites, then migrate north with the retreating pack ice to feed. Annual round-trips may cover 4000 km, although there is much variation in migratory distance and route among individuals and populations throughout the North Atlantic. Northern elephant seals hold the current record for the longest migration of any mammal: 18–21,000 km annually as they move twice between Californian islands used for breeding (January–February) and molting (July–August) to higher-latitude feeding areas rich in cephalopod prey (Stewart and DeLong, 1995). Northern fur seals, perhaps the only true migrants among the otariids, migrate in the opposite direction of most phocids, breeding at higher latitudes in the summer months and migrating south to temperate waters to overwinter (Gentry, 1998).

Although clearly not mammals, sea turtles closely resemble pinnipeds in their migratory behavior. Adults migrate to specific island or continental beaches where eggs are laid. Hatchlings venture immediately to the sea where they may

spend 30 or more years before maturing and returning to the same beach to complete the cycle (Meylan *et al.*, 1990).

Tropical marine mammals, such as dugongs and manatees, are generally nonmigratory, although the West Indian manatee (*Trichechus manatus*) population in Florida may move several hundred kilometers north in summer to exploit new feeding areas, retreating back to warmer waters in the winter (Reynolds, 1999). Their need for warm water in which to overwinter has in some cases made them dependent on the warm-water discharges of coastal power plants.

Fish and Other Aquatic Species

Fish show a range of migratory patterns, both among different species and different populations of the same species (McKeown, 1984). Migration is relatively common in this group, particularly as a means of linking rich feeding habitats with specialized spawning grounds that provide refuge for eggs and young fish. For diadromous species – the most studied and conspicuous migratory fishes – this journey requires moving from marine to freshwater environments in order to breed (anadromous: e.g., salmonids, shad, sticklebacks, lampreys) or, more rarely, the converse (catadromous: e.g., freshwater eels, southern trout, southern smelt). Anadromous species predominate in cold-temperate and subpolar waters in both hemispheres, while catadromous species more commonly occur in warm-temperate and subtropical waters (McDowall, 1988). The benefits of moving from lower to higher productivity habitats to feed and grow may account for this pattern since marine productivity is higher at high latitudes while freshwater productivity is higher at low latitudes (Gross *et al.*, 1988). Anadromous species constitute a higher proportion of total coastal fish diversity in the Pacific than they do in the Atlantic, largely due to the Atlantic's much higher coastal fish diversity overall.

As with marine mammals (e.g., baleen whales), migrant fishes with separate feeding and spawning areas must feed intensively and store sufficient energy reserves for both migration and spawning. Although many species migrate only a few kilometers between feeding and breeding sites, some fish migrations are truly remarkable in length. Upstream distances in diadromous species include 300–400 km in lampreys, 500 km in shad, and well over 1000 km in some salmon and sturgeons (McDowall, 1988). Sockeye salmon migrating upstream expend 70% of their available energy in reaching the spawning grounds and the rest on spawning itself (Brett, 1986); not surprisingly, both sexes die shortly thereafter. The combined toll of fasting, migrating upstream, and spawning results in semelparity for most diadromous species (McDowall, 1988), but some species, such as the Atlantic salmon (*Salmo salar*) and northern populations of American shad (*Alosa sapidissima*) may migrate and spawn more than once (Wootton, 1990). The dramatic physiological transition required to move between freshwater and marine environments may also be a factor in the prevalence of semelparity among diadromous species.

Salmonid migrations typify anadromous life cycles, but they also illustrate the very flexible migratory strategies of fish (McKeown, 1984). Pacific salmon (*Oncorhynchus* spp.) spawn

in streams at cold-temperate and subpolar latitudes on both sides of the Pacific. After hatching, they either (1) travel immediately downstream to the ocean or, (2) before migrating to the ocean, move downstream to lakes where they spend the next 2–4 years, or (3) remain in their hatching stream for 1 or more years. Once in the ocean, some species migrate the breadth of the Pacific to reach feeding areas while others remain closer to their spawning streams; accordingly, the time spent feeding and growing in the marine environment varies among species but is generally 2 or more years. The same species may have several distinct upstream migrations throughout the year. Further variation on this pattern is shown by individuals (e.g., sockeye salmon: *Oncorhynchus nerka*) that never migrate to the ocean but remain in lakes and move upstream to spawn with ocean-returning migrants. In contrast to other anadromous fish, such as shad and lampreys, salmonid ancestors resided year-round in freshwater and evolved the ability to migrate to marine habitats, perhaps accounting for the great variety of migratory strategies now seen in this group.

The best known catadromous migrants are the freshwater eels (*Anguilla* spp.). They occur throughout the world, including North America and Europe where most studies of their life cycles have been conducted (McCleave and Kleckner, 1985). In North America, adult eels live in rivers and brackish estuaries from the Gulf of Mexico to Labrador, migrating into the Atlantic to spawn. The actual spawning sites still remain a mystery, but small larvae (leptocephali – once thought to be a separate species with no affinity to eels) have been found in the Sargasso Sea, suggesting spawning is here or very nearby. Over the first year, currents carry the leptocephali toward in-shore habitats where they metamorphose into glass eels and leave the marine environment. After several years in fresh water, they are ready to migrate, spawn, and complete the cycle, dying after they spawn. Interestingly, adult females are found at greater distances from the spawning grounds – further up rivers, in lakes, and at higher latitudes – than adult males and should thus have greater costs of migration (Helfman *et al.*, 1987). Females also grow larger at maturity suggesting very different life history strategies for the two sexes.

Oceanodromous species, or those that migrate throughout the marine environment alone, often travel complex migratory circuits between sites optimal for different stages of the annual or life cycle. Ocean currents and coastal topography shape these movements, and those of prey items, adding further complexity to the annual migratory pattern. For example, Atlantic herring (*Clupea harengus*) have numerous northern subpopulations, each with distinct spawning and feeding grounds and each following its own migratory route and schedule without intermingling to any great extent (Baker, 1978). Immature fish have separate migrations, moving in-shore during warmer months and offshore to deeper waters during winter. On reaching maturity, they follow the migratory circuit of their parents. Other oceanic long-distance migrants include cod (*Gadus morhua*) and plaice (*Pleuronectes platessa*) at higher latitudes and several tuna species in temperate and tropical waters. In most cases, these migration circuits are of the order of 1000–3000 km in diameter (McKeown, 1984). Littoral migrations also occur commonly among oceanodromous species, but they are generally much

shorter. Those species moving to track food resources usually move offshore in winter, while species migrating inshore during winter may do so to spawn in relatively predator-free habitats.

Species living solely in freshwater (i.e., potamodromous) commonly migrate from deep to shallow waters in order to spawn. A large variety of potamodromous fish migrate throughout the world's lakes and rivers, including freshwater rays, sturgeons, suckers, minnows, pikes, sunfishes, darters, perches, and catfishes. Shallower, upstream habitats may exclude certain predators or have water characteristics (e.g., oxygen, temperature, or silt levels) more suitable to the development and growth of eggs and young fish (McKeown, 1984). The South American characin, *Prochilodus mariae*, has both nonmigratory, lake-breeding and migratory, stream-breeding individuals within the same population. The observation that lake breeders expend five-times more energy on egg production than stream breeders suggests that stream habitats provide sufficient benefits in offspring survival to compensate for the high energetic costs of migration (Saldana and Venables, 1983).

Beyond fish and marine mammals, migration in aquatic animals is less common – or perhaps just understudied. Spiny lobsters in the family Palinuridae demonstrate a very curious migratory behavior, queuing up in long lines of up to 50 individuals that snake their way along the ocean bottom toward deeper, more sheltered habitat. These movements, as much as 30–50 km in length over several days, usually occur seasonally in response to a greater incidence of polar storm fronts, which bring colder water temperatures and greater wave disturbance to the shallow water habitats the lobsters feed in during warmer months. Migration thus allows spiny lobsters to exploit a resource-rich, yet seasonally stressful, habitat (Herrnkind, 1985).

Plankton show distinct migrations in the water column driven by the seasonal availability of nutrients (Angel, 1985). During months of high productivity, plankton migrate to surface waters; as productivity declines, they return to lower depths and often enter into a state of diapause. Since changes in light work in concert with endogenous rhythms to set the schedule for these movements, the maximum depth reached during the nonproductive season will depend on how far light penetrates the water. In the Northeast Atlantic, typical maximum depths are 1200 m (Roe, 1983). Seasonal planktonic migrations are most prevalent at higher latitudes and in regions where currents cause seasonal upwellings of nutrients. (Many planktonic species demonstrate diel vertical “migrations” in the water column (Huntley, 1985), but because these constitute daily ranging movements rather than migrations by the definition given earlier, we do not consider them further.)

Amphibians and Reptiles

Amphibian life cycles often require a return to water to reproduce, resulting in migrations from feeding areas or refugia to seasonal ponds, streams, and other water sources (Stebbins and Cohen, 1995). However, salamanders and anurans are not known for their great mobility and consequently most species do not travel far from where they were

born. Red-bellied newts (*Taricha rivularis*) may hold the distance record for their migrations of 1 km from feeding range to breeding site (Twitty *et al.*, 1967). Similar migrations in anurans may extend several kilometers. Still, migrating anurans are remarkable for their fidelity to specific breeding sites and the precision with which individuals are able to return to the same few meters of shoreline each year.

Lizards very rarely migrate, but those that do also move to seek out suitable nesting sites. Green iguanas and a few related species that nest on islands may move as much as several kilometers to lay eggs at specific sites; the scarcity of appropriate soil in their island habitat presumably drives these migrations (Rand, 1968). The red-sided garter snake (*Thamnophis sirtalis parietalis*) migrates to winter hibernacula, such as limestone sinkholes, aggregating in the thousands to buffer the harsh winter conditions of Manitoba (Aleksiuk, 1976).

Insects and Other Terrestrial Invertebrates

Our current state of knowledge regarding insect migrations contains a number of spectacular examples but gives the overall impression that the phenomenon is not common in this group despite its huge contribution to our planet's biodiversity. Well-known examples include the Eurasian milkweed bug (*Lygaeus equestris*) and the North American ladybird beetle (*Coleomegilla maculata*), which perform seasonal movements from summer feeding and breeding sites to more protected areas a few kilometers away (Solbreck *et al.*, 1990). There they diapause and last out the winter surviving on stored fat. Individuals may coalesce at specific sites and form spectacular aggregations. As in other migratory species we have considered, migration allows both species to exploit rich, but seasonally variable, habitats. Because many insects have highly specialized feeding and breeding requirements, even small seasonal variations in temperature, moisture, and light levels may be sufficient to trigger migrations to sites where individuals can wait for local conditions to improve (i.e., diapause). The general migration pattern illustrated by ladybirds and milkweed bugs may thus be widespread among both temperate and tropical species. However, small insects are likely to migrate only short distances and be overlooked and understudied, especially if migrations occur without individuals aggregating into conspicuous groups.

An alternative migration pattern takes individuals from habitats declining in quality to richer sites that allowing feeding and breeding to continue. Among the noctuid, or armyworm, moths – a group found throughout the world – several species follow annual round-trip migratory circuits of several-hundred kilometers that take them to successively higher latitudes or to habitats recently freshened by rain with host vegetation more suitable for breeding (Gatehouse, 1987). In many cases, these species have become significant agricultural pests having a life history ideally suited to quickly exploiting ephemeral but rich food sources. Interestingly, single generations may complete only part of the migratory circuit, raising fascinating questions regarding the evolutionary genetics of migration timing and navigation. Perhaps the most famous migrant of this type is the monarch butterfly, *Danaus plexippus*, of North America (Brower and Malcolm, 1991).

Monarch larvae feed on milkweeds and the timing of migration coincides with seasonal milkweed growth. In autumn, adult butterflies from as far north as eastern Canada migrate more than 1000 km south to overwinter in huge aggregations at only a few critical sites in the mountains of central Mexico. In spring, these same adults migrate 200–300 km to the northern edge of the Gulf of Mexico where they breed and die. Successive generations then move north tracking the milkweed growing season.

When large-scale migrations occur in insects, they are truly astounding behaviors if one considers the size of the travelers and the distances covered. Because insects have only limited capacity for fuel storage, they depend to a great extent more than other migrants on winds to propel and direct their movements. North American aphids, for example, fly for 2–24 h and travel from 50 to 1100 km before setting down. Differing wind speeds at different altitudes account for the variation in flight time and distance moved, but aphids probably exert some control over these features by choosing an altitude at which to fly.

In response to deteriorating local conditions, either due to seasonal reductions in food or increased densities, some insects develop long-winged (i.e., macropterous) forms able to travel relatively large distances to find more suitable habitat. Examples include planthoppers and aphids. These irruptive movements also occur in other taxa, such as birds, but they resemble dispersal processes more than the migrations we have so far considered.

Terrestrial crustaceans, such as hermit crabs and ghost crabs, must migrate from nonbreeding, feeding habitats to high-salinity water in order to breed. These movements occur seasonally, especially in response to tidal cycles, and may require movements from 10 to 3000 m each way (Wolcott and Wolcott, 1985).

Consequences of Migration

When animals collectively move in directed ways from one area to another, they connect disparate habitats. When they do so they not only can transfer large amounts of nutrients between ecosystems, but also they can transfer other species as well. And when these hitch hikers are pathogens, the implications for the dynamics of infectious diseases can be profound (Altizer *et al.*, 2011). Cases exist of migrants enhancing the movement of pathogens, including those that may affect human health. Some of the best known are Lyme disease and West Nile virus that moved up and down the east coast of the US from a point of origin in New York City (Rappole *et al.*, 2000; Owen, 2006) and Saiga deer of Kazakhstan that become infected with intestinal worms after moving into areas previously grazed by domestic sheep and then once infected continue to pass the parasites on to other sheep herds along their migratory route (Morgan *et al.*, 2000). But the importance of such transmission to other species may be overestimated. Because pathogens may kill infected migrants before they arrive at their destination or disease agents may be purged from the migrant's system before arrival by virtue of the pathogen's own biology, the actual extent of migrant assisted disease transmission may be limited (Altizer *et al.*, 2011).

Yet migrants are likely to suffer high rates of infection while en route because few species travel nonstop. By stopping to “refuel”, at widely spaced and highly restricted sites, migrants create large aggregations that increase disease spread from one migrant to another. And if humans continue to degrade habitats and reduce the number of stop over points, remaining stop over points are likely to become even more effective at spreading disease.

Changes in climate are also likely to alter the way migrants influence disease dynamics. On the one hand, if humans continue to change climate so that migratory ranges expand, then new contacts among previously separated species are likely to have dramatic negative consequences. On the other hand, massive changes in climate or habitats could reduce the benefits of migration so that migration ceases, thus subjecting the transformed sedentary population to higher levels of infection. In monarch butterflies, for example, parasite prevalence and virulence increase with longer residency and more intense habitat use. Thus, milder climates could lead to greater and more devastating infections in emerging nonmigratory populations (Altizer *et al.*, 2000) or if habitat change positions increased parasite reservoirs in areas of species overlap, then greater species to species transmission is likely. Such a process of sedentarization resulting from local habitat enhancement has been implicated in triggering the spread of Nipha virus from flying foxes to pigs to humans (Plowright *et al.*, 2008). Whether or not environmental change enhances or limits the spread of disease, will depend on life history traits of parasites and hosts and contact rate among migrants and other members of the communities they connect.

Attributes of Migrants Affecting Susceptibility to Human Disturbance

As we have seen, migrations appear to serve a few common functions. In general, they enable species to temporarily avoid harsh conditions or to meet important biological needs that are separated by great distance. Not surprisingly, there are certain attributes of migrants that affect their susceptibility to human disturbance.

First, migratory species often use a variety of habitats, leaving them vulnerable to multiple points of disturbance. Often harm is felt mostly at one destination. Bachman’s warbler (*Vermivora bachmanii*), for example, was driven to extinction by the destruction of its overwintering habitats in the tropics. For others, however, such as many Neotropical migrant birds, the impacts of human activities are felt at both endpoints of their migrations. Globe-trotting species like the white-rumped sandpiper typify the precarious dependence of migrants on habitat health across a tremendous geographic scale. But harm need not be limited to the endpoints of a migrant’s journey. Any diminution in quality of refueling sites along the way could winnow a population and limit its ability to replenish its numbers before the next cycle of migration. And given that migratory trajectories for many species are shaped by the vagaries of prevailing winds or currents, conservation strategies entailing the protection of all stopover areas becomes almost impossible. Even where resting points are protected, unintended consequences associated with the

normal nonintrusive behavior of naturalists can put migrants at risk. Steady viewing by bird watchers at refuges along coastal fly routes has been known to force birds to move too far offshore where they can no longer feed on inshore marine invertebrates exposed at low tides.

Sea turtles probably illustrate the best effects of migratory species being vulnerable at many life-history stages to the excesses of human behavior. Not only are their eggs sought after and easily harvested by indigenous peoples, but also the beaches themselves are often degraded by the activities of affluent humans. Entire breeding populations are eliminated when beach habitats are developed or severely compromised in their abilities to launch young when dune buggies destroy nests or excessive night lighting disrupts the water-seeking behavior of newly hatched young. In addition, for those young that mature to subadults and return to the breeding grounds, nets of fishermen, particularly shrimpers, provide the *coup de gras* to the species by drastically reducing the pool of future breeders. In fact, it has been shown for that the most vulnerable period in the life cycle is not the nestling, but rather the subadult, stage (Crouse *et al.*, 1987). Although protecting beaches and increasing the number of functioning beaches gives the species a head start by diversifying recruitment sites, sea turtles are most vulnerable to extinction if the number of subadults is reduced. It is at this point in the species’ life history where a long life of breeding commences and reproductive value is highest. Only by insisting that shrimpers insert turtle excluder devices (TEDs) in nets so that the turtles can escape before drowning will there be any hope that those migratory species already endangered will survive.

Second, migratory species often aggregate when traveling. While this behavior might reduce each individual’s risk of falling prey to nonhuman predators, both aquatic and terrestrial species in groups are easy targets for the advanced harvesting gear employed by commercial fishers and hunters. In prehistoric times, hunters stampeded herd animals off cliffs and into canyons where massive kills occurred. Such actions have been implicated in the extinction of many of the North American megafauna. Today even the smaller, more elusive, and difficult to capture prey are at risk. Many marine fisheries involving migratory schooling fishes, such as those of cod and haddock, have been overfished. And despite moratoria, many are not recovering.

Third, since many migratory species move according to very precise schedules, any delays caused by human alteration of the habitat or disruption of normal movements could lead to a cascade of effects, jeopardizing a species’ ability to replenish its population numbers reduced by ordinary mortality. As noted earlier, migrating shorebirds if forced to linger longer at refueling refuges, could have breeding seasons shortened sufficiently to lose the ability to lay one or more clutches. And since selection favors renesting because nest predation rates are already high, any force constraining such efforts could severely limit a species’ recruitment potential.

Despite these attributes that threaten species survival there are some beneficial traits exhibited by migrants. By occupying, at least temporarily, many different habitats, migrants can spread risks and thus can escape catastrophes that befall one location. Unless all individuals in a species simultaneously occupy the same habitat, survivors from habitats not impacted

by the catastrophe can serve as sources for increasing species numbers. Migratory species are also more likely to find and colonize new habitats as they are opened up by climate change or other human-induced and natural changes in the environment.

Ecological Consequences of Human Disturbance on Migrants

As humans fragment landscapes, many migratory species will find themselves in peril. For species that must move from one region to another in order to meet a variety of biological needs, any barrier disrupting these movements could lead to local extinctions. In southern Africa, fences are being built either to prevent mixing of wildlife and livestock and the concomitant transmission of disease (ensuring that exported beef is disease free) or to prevent wildlife from gaining a competitive edge over livestock when both compete for critical resources such as food near water. Without access to these resources at the time of year most critical for developing juveniles, any migratory population's recruitment will be severely curtailed. Many local populations will either go locally extinct or will be transformed from "sources" of new emigrating individuals to "sinks" where excess individuals from healthy populations find refuge. Even for populations that still boast numbers in the hundreds of thousands, such as the plains zebra or even African elephants (*Loxodonta africana*), fragmentation of the large populations is well underway. With human populations expanding into habitats only marginally suited for horticulture, the cry for fencing areas to prevent crops being consumed by migrating herbivores is increasing.

When the movements of these populations are disrupted, a cascade of indirect effects on both the recycling of nutrients in ecosystems and the structuring of animal communities are likely to occur. Since migratory species represent some of the largest aggregations and highest densities of individuals seen in the animal world, any disruption to migration is likely to reduce local density. Thus, it is quite possible that the important impact on the structure of vegetation, or more generally the recycling of nutrients, will be altered (Augustine and McNaughton, 1998). It has even been proposed that the overharvesting of sperm whales and the removal of their large carcasses from the ecosystem have impacted the community stability of the deep-sea communities associated with deep-sea vents. By preventing carcasses from falling to the ocean floor, an important source of renewing "island" resources has been eliminated, thus making it more difficult for species tightly associated with vents to hop from one vent to another (Butman *et al.*, 1995). With respect to structuring communities, if plains zebras are unable to move in large numbers across the landscape from the tops of catenas where they forage during the rains to the wetter valleys where they move when the rains cease, then their facilitative effect on diversifying the herbivore community will be reduced. Typically, plains zebra move to the wetter valleys and graze down the tougher, fibrous forage that dominates these areas making the greener and more nutritious forage available for the ruminants that require such higher quality vegetation. Thus, by disrupting the movements of such a "keystone" species, the

diversity of large grazers could be reduced (Rubenstein, 2010). Furthermore, exclosure experiments suggest that the grazing community could shift from one dominated by large ungulates to one populated by small rodents and lagomorphs (Keesing, 1998). Since rodents often come in contact with people and harbor human diseases, the cascade of effects could be quite profound.

Perhaps one of the greatest impacts of disrupting movements will be seen via the effects that elephants have on the landscape. As populations become restricted to reserves if their numbers are allowed to increase, then their ability to transform a mosaic landscape of trees and grasslands into one of mostly grasslands will mean the disappearance of resident forest- and woodland-dwelling species of colobine monkeys and antelopes.

Even for those subdivided populations that can adapt to the nonmigratory habit – and in certain places such as the Ngorongoro Crater in Tanzania, resident and migratory populations of zebra, Thompson's gazelle, and wildebeest coexist – genetic effective population sizes will shrink and the loss of heterozygosity could leave the population vulnerable to the emergence of novel diseases or the devastating effects of inbreeding. The trend to isolate migratory wildlife into reserves that are too small, although serving as an immediate panacea to human population expansion and development, could have adverse long-term consequences for the health and survival of species unless they are designed to be of appropriate size or have appropriate corridors for migration included in their design. The creation of multinational parks in South Africa, Mozambique, and Zimbabwe that include important mixes of habitats required by a wide variety of migratory species is on the drawing board and offers some hope that subdivision and isolation of populations will be reduced.

Migratory species are also likely to be directly affected by global climate change. It has been suggested that the arctic tundra as a habitat might disappear (Peters, 1991). If the upper 2–3 m of permafrost, which helps bind the tundra together, were to disappear, then the tundra as a habitat would vanish. The effects would drastically reduce populations of caribou that traverse large distances across it as they move from summer breeding to more protective wintering feeding sites. Such transformations of animal communities have occurred in the past when climates have dramatically changed and migratory species were excluded from important parts of their ranges. For example, much of the Canadian–Alaskan megafauna vanished 10–20 million years ago when the forests closed and sedge and other patchy but nutrient-rich herbaceous species disappeared. But the scope of these impacts is likely to be greater in the near future because both the magnitude and rate of change associated with the climate effect is increasing and is being coupled with widespread land-use changes that are occurring in areas where the migrants will be forced to move.

Evolutionary Consequences of Human Impacts on Migrants

While it is clear that human behavior disrupting migrations will have ecological consequences, the effects on the evolutionary potential, or even the future characteristics, of

species are also likely to be large. Nowhere is this impact more evident than in North America where the range of the bighorn sheep has been severely reduced and fragmented. Bighorn migrate seasonally from meadows to mountaintops to avoid harsh climate and in search of grass that changes seasonally in quality at each location. As human populations have expanded, populations have been isolated into refuges, numbers are shrinking, and genetic diversity is being lost (Primack, 1993). In addition, hunting for trophy males is removing just those individuals with the best and most diverse genotypes. As a result, the ability of the isolated populations to remain genetically diverse enough to forestall problems associated with inbreeding or to avoid the ravages that would occur if a novel disease appeared has been severely compromised.

Migratory Atlantic salmon (*Salmo salar*) provide perhaps the clearest example of where human activities are causing a species to change under our own eyes. Atlantic salmon typically are born in fresh water and develop for 1–2 years before smolting and heading to sea to grow and fatten by feasting on a rich supply of marine invertebrates. Once they attain a certain size, they become sexually mature and return to rivers. There they travel long distances upstream until they reach clear and cool breeding grounds. Some individuals, however, never head to the sea. Instead, they remain in their natal streams and mature sexually at young ages and at small sizes. Such individuals are called parr and they never go through the smolting process that adapts them to a marine lifestyle. Under pristine environmental conditions, the fraction of the population that becomes parr is small since the reproductive gains of such a strategy are low. When competing for mates with larger more aggressive males, parr fare poorly. What matings they obtain are derived by “sneaking” among a mating pair and releasing milt at just the right time. Such events are rare and the mixing of milt is poor so such sneak matings result in few young being sired by parr. But the survival prospects of parr are high since they do not incur the risks of going to sea and, moreover, they begin breeding at a very early age. Thus, over a lifetime, reproductive success is modest. But as human fishing increases and the netting of the older larger salmon intensifies, the relative lifetime reproductive success of parr is improving. Since the costs of migrating to sea and back again have increased dramatically, the long life span of parr gives them a relative advantage. And given that competition with the larger males for mates is also declining, the chances of parr securing matings are also improving. Thus, it is not surprising that the composition of the population is changing as parr increase markedly in abundance. The impact on the long-term stability of the population is unclear. But the long-term impact on the species appearance is clear, just as it is for yet another fishing industry that will go into decline as the large fish disappear.

Glossary

Climate Change Refers to a statistically significant variation in either the mean state of the climate or in its variability, persisting for an extended period (typically decades or longer).

Deforestation The removal of a forest stand where the land is put to a nonforest use.

Ecological succession The process by which an ecological community undergoes more or less orderly and predictable changes following disturbance or initial colonization of new habitat.

Forest fragmentation When forests are cut down in a manner that leaves isolated patches of forest known as forest fragments or forest remnants.

Sustainable forest management The stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality and their potential to fulfill, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems.

Tropical seasonally dry forests Forests in the tropical region characterized by pronounced seasonality in rainfall distribution with several months of drought.

Introduction

Tropical seasonally dry forests (TSDFs) are considered one of the most threatened forest ecosystems in the world as a consequence of intensive anthropogenic disturbance (Janzen, 1986; Murphy and Lugo, 1986, 1995; Hoekstra *et al.*, 2005; Miles *et al.*, 2006; Portillo-Quintero and Sánchez-Azofeifa, 2010). Their fertile soils and mild climates make them highly suitable for agriculture and livestock (Murphy and Lugo, 1995; Ewel, 1999; Piperno and Pearsall, 2000). In TSDF, annual rainfall does not deviate greatly from potential evapotranspiration; therefore water for irrigation is needed in modest amounts only during the dry season (Ewel, 1999). Given its attractive environmental characteristics for human settlement and development, these ecosystems have historically supported extensive deforestation and high human population densities (Tosi and Voertman, 1964; Janzen, 1986; Quesada and Stoner, 2004; Sánchez-Azofeifa *et al.*, 2005b).

TSDFs have several definitions. According to the Holdridge life zone system, TSDFs have a biotemperature greater than 17 °C, an annual precipitation of 500–2000 mm, a potential evapotranspiration ratio of between 1 and 2 (ratio of mean potential evapotranspiration to mean annual precipitation; a measure of humidity), and a dry season that lasts 4–6 months (Holdridge, 1967; Janzen, 1983; Lüttge, 1997). According to Mooney *et al.* (1995) TSDFs are forests in the tropical region characterized by pronounced seasonality in rainfall distribution with several months of drought. Moreover, Sánchez-Azofeifa *et al.* (2005b) defines TSDF as a vegetation type dominated by deciduous trees where at least 50% of trees present are drought deciduous, the mean annual biotemperature is > 17 °C, total annual precipitation ranges between 700 and 2000 mm, and there is the presence of three or more months every year with less than 100 mm of rainfall. Sánchez-Azofeifa *et al.* (2005b) also considers savannas,

gallery forests, coastlines and mangroves among the associated vegetation types that can occur within the matrix of NSTFs. According to Pennington *et al.* (2006), TSDF is a tropical vegetation type that experiences a minimum dry season period of 5–6 months with concomitant strongly seasonal ecological processes and functions. The latter definition includes diverse vegetation formations such as forests within grasslands, shrublands, and savanna ecosystems as in Sánchez-Azofeifa *et al.* (2005b); from tall forests on the more humid dry forest sites to cactus scrub on the driest.

Despite TSDF remarkable richness of species, including endemic species, alarming deforestation rates, and the importance of its ecosystem services to sustain economic development for many regions with high population densities, it is surprising to realize how far knowledge of the ecology, the human and biophysical dimensions about this important ecosystem lags behind that of other tropical forest biomes (Murphy and Lugo, 1986; Quesada and Stoner, 2004; Sánchez-Azofeifa *et al.*, 2005b; Miles *et al.*, 2006; Quesada *et al.*, 2009; Portillo-Quintero and Sánchez-Azofeifa, 2010; Balvanera *et al.*, 2011; Chazdon *et al.*, 2011). As of 2005, only 14% of all scientific publications on world tropical forest research focused on TSDF, whereas 86% referred to wet forests (Sánchez-Azofeifa *et al.*, 2005b). In addition, no publications on the effect of climate change on TSDFs or the quantification of ecosystem services were part of the body of knowledge until that specific moment.

According to Miles *et al.* (2006), more than 54% of world's TSDFs are located in the Neotropics, where large continuous fragments still remain and most scientific studies and conservation efforts have taken place. This article refers to seasonally dry forests in the Americas or Neotropical seasonally dry forests (NSDFs). In the next sections, the general physical and biotic characteristics of NSDF as well as the characteristics of its successional stages are described. Patterns and processes of land-use/cover change such as extent, fragmentation

patterns, degree of protection, drivers of change, and issues aspects of silvicultural management are explored.

In addition, this article includes information on the extent and distribution of forest vegetation outside the strict NSDF bioclimatic limits following [Portillo-Quintero and Sanchez-Azofeifa \(2010\)](#). In their study, tropical and subtropical forests within important associated savannas, grasslands, and shrublands ecosystems such as the Chaco dry forests, Caatinga, Cerrado, the Llanos, and other savannas in South America were included. These ecosystems are considered areas where NSDF species could potentially occur ([Miles et al., 2006](#)).

NSDF Structural and Compositional Characteristics

When compared with wet forests, NSDF present some unique characteristics:

- NSDF defy the well-established trend of increasing species richness as one approaches the equator ([Fischer, 1960](#); [Gentry, 1988 and 1995](#); [Chazdon and Denslow, 2002](#)). The most diverse NSDF are located farther from the equator ([Gentry, 1988 and 1995](#)), been on the Pacific Coast of Mexico a hotspot of NSDF biodiversity worldwide.
- In NSDF, species richness is higher among the driest sites. For example, a greater diversity has been found in Chamela Mexico and Quiapaca Bolivia than from sites that receive more precipitation such as Guanacaste, Costa Rica ([Gentry, 1995](#); [Lobo et al., 2003](#)).
- NSDFs have a high degree of floristic endemism. For example, the estimates of endemism had been as high as 43% in Mexico ([Rzedowski, 1991](#)) or 70% in South America ([Gentry, 1982](#); [Joly, 1970](#)). More recently endemism patterns for NSDFs have been confirmed by the study of [Linares-Palomino et al. \(2011\)](#). The main conclusions of [Linares-Palomino et al. \(2011\)](#) is that 12 of 23 neotropical geographical nuclei have more than 20% of unique species (a proxy for level of endemism), the highest nuclei being Insular Caribbean (77.5%) and Mexican Pacific (65.5%) in the north, and Equatorial Pacific (47.1%) and Peruvian Inter Andean Valley (46.4%) in the South.
- NSDF plant species show specialized structural and physiological strategies to cope with the seasonal reduction of soil moisture and increase in evapotranspiration demands. These include higher wood density, greater root biomass, and deeper root systems than plant species in humid forests, stem water storage, and hydraulic architecture, as well as complex dynamics of leaf abscission, timing of leaf fall, flowering, and shoot expansion ([Holbrook et al., 1995](#)).
- The *Fabaceae* is consistently the dominant tree family (except for the Caribbean islands where the *Myrtaceae* family predominates). The *Bignoniaceae* is the dominant liana family, but their relative dominance is greater in NSDF as compared to humid forests due to its lower species diversity ([Gentry, 1995](#); [Lugo et al., 2006](#)).
- NSDFs have extremely high β -diversity or spatial species turnover: of 21 NSDF geographic nuclei in the Neotropical region, 80% of all possible pairs (253) have dissimilarity values greater than 70% ([Linares-Palomino et al., 2011](#)).

Table 1 Structural and functional characteristics of tropical and subtropical dry and humid (wet/rain) forest

Characteristics	Forest type	
	Dry ^a	Wet ^b
Structural characteristics		
Number of species ^c	35–90	50–200
Canopy height (m)	10–40	20–84
No. of canopy strata	1–3	3
Basal area (m ² ha ⁻¹)	17–40	20–75
Leaf area index (m ² m ⁻²)	3–7	5–8
Plant biomass (t ha ⁻¹)		
Stems and branches	28–266	209–1163
Leaves	2–7	7–10
Roots	10–45	11–135
Total	78–320	269–1186
Root biomass as % of total	8–50	5–33
Functional characteristics		
Net total primary productivity (t ha ⁻¹ yr ⁻¹)	8–21	13–28
Fine litter production (t ha ⁻¹ yr ⁻¹)	3–10	5–14
Tree diameter growth (mm yr ⁻¹)	1–3	2–6

^aAnnual rainfall 500–2000 mm; strongly seasonal; annual PET/P normally > 1.

^bAnnual rainfall > 2000 mm; little or moderate seasonality; annual PET/P normally ≤ 1.

^cBased on surveys of 1–3 ha; includes trees at least as small as 10 cm dbh.

Source: Adapted from [Murphy PG and Lugo AE \(1986\)](#) Ecology of tropical dry forest. *Annual Review of Ecological Systematics* 17: 67–88.

- Structure of NSDF is characterized by smaller trees, lower basal area, diameter growth, biomass, and productivity than wet forests ([Table 1](#)), but they tend to be more similar with respect to tree density (i.e., number of trees per hectare) ([Gentry, 1995](#)). For example; continental NSDFs have the same average number of plants 2.5 cm in dbh in 0.1 ha plots as do humid forests (370 vs. 373), the same number of trees 10 cm dbh (65 vs. 64), the same number of lianas 2.5 cm diameter (72 vs. 68), and only slightly lower basal area in m² ha⁻¹ (34.7 vs. 40). However, average root biomass as a portion of total plant biomass is greater in TSDF (33.5% with a range of 8–50%) than in wet forests (16% with a range of 5–33%) ([Holbrook et al., 1995](#)).

On average, NSDF species richness is close to 64 (range 21–121); subdivided in: tree richness of 50 sp. (range 21–81) and lianas richness 15 sp. (range 0–37) ([Gentry, 1995](#)). The most important families in order of dominance are: *Fabaceae*, *Bignoniaceae*, *Rubiaceae*, *Sapindaceae*, *Euphorbiaceae*, *Flacourtiaceae*, *Capparidaceae*, *Apocynaceae*, *Nyctaginaceae*, *Polygonaceae*, *Malpighiaceae*, and *Cactaceae*. The most representative genera on Gentry's plots were: *Tabebuia*, *Cordia*, *Casearia*, *Bauhinia*, *Trichilia*, *Erythroxylum*, *Randia*, *Hippocratea*, *Serjania*, *Croton*, *Zanthoxylum*, *Arrabidaea*, *Celtis*, *Capparis*, *Combretum*, *Pithecellobium*, *Pterocarpus*, *Paullinia*, *Bursera*, *Coccoloba*, *Macfadyena*, *Eugenia*, *Acacia*, and *Ficus*; *Tabebuia* being the most widespread genus.

NSDFs have larger diversity of life forms than humid forest ecosystems, likely a consequence of habitat heterogeneity in water availability, with woody deciduous components being the dominant type. Tropical moist and wet forest include six major life forms; evergreen woody plants, deciduous woody plants, lianas, C3 epiphytes, crassulacean acid metabolism (CAM)

epiphytes, and hemiparasites; whereas NSDF includes nine life forms: evergreen woody plants, deciduous woody plants (40% of the woody species), sclerophyllous woody plants, succulent woody plants (including cacti), herbs, rosettes, lianas, CAM epiphytes, and hemiparasites (Medina, 1995).

Other characteristics of NSDF are the high proportion of wind-dispersed species (i.e., anemochorous species). According to Gentry (1995), 80% of the lianas and a third to a quarter of the trees are wind dispersed, contrasting with the figures for the humid forest where 90% of the trees and 75% of the lianas are zoochorous (i.e., spores or seeds are dispersed by animals). Also, from about two-thirds to three quarters of NSDF woody taxa have conspicuous flowers, which are pollinated by hawkmoths, bats, and large and medium size bees (Bullock, 1995).

Most of the ecological processes in NSDF are seasonally driven, and depend on the length and intensity of their dry season. Leaf litter biomass builds up during the dry season, flowering and fruiting phenologies occur in specific moments of the year and many flower species blossom at the same time during the transition between dry and wet season (Pennington *et al.*, 2006; Bullock, 1995; Mooney, 1995). In the driest sites, there is an increase in the proportion of evergreen and succulent species.

Animal Diversity

According to available comparable data from 10 selected study sites (Ceballos, 1995), NSDF have on average less vertebrate species diversity than moist and wet forests: total species (443 vs. 630), mammal sp. (88 vs. 113), birds sp. (287 vs. 404) and herptiles sp. (67 vs. 112). All animals in NSDF exhibit diverse means to adapt to the reduction of available food and water resources during the dry season (Ceballos, 1995; Stoner and Timm, 2011). These adaptations might include one or a combination of several strategies: latitudinal or elevation movements, shifts in diet to utilize seasonally available food resources, seasonal accumulation of fat or food resources, reproductive delay, behavioral and physiological adaptations. Wildlife trade, hunting, forest fires, pesticide contamination, destruction and fragmentation of NSDF habitats are the major problems affecting conservation of biodiversity (Ceballos, 1995; Stoner and Timm, 2011; and Chazdon *et al.*, 2011).

A large proportion of all insects in tropical forests are phytophagous or parasitoids of other phytophagous insects. According to Hanson (2011), the majority of insect families are probably more species rich in humid forests than in NSDF because plant species richness is greater in humid forests. Some NSDF characteristics can affect insect diversity; for example, the quality of dead wood in the forest floor (Dynastinae family diversity), soil physical and chemical characteristics (insect taxa with soil-inhabiting larvae), and reduced number of epiphytes (ant diversity).

Secondary Succession in NSDF

Many NSDF can no longer be considered pristine old-growth forests, but rather as a mosaic of successional stages due to

extensive anthropogenic disturbances, particularly Mesoamerica and the Caribbean (Janzen, 1986, 1988; Arroyo-Mora *et al.*, 2005a,b; Quesada *et al.*, 2009; Calvo-Alvarado *et al.*, 2009). Recent studies have also shown that NSDFs are recovering in some areas through natural restoration (Abizaid and Coomes, 2004; Arroyo-Mora *et al.*, 2005a,b; Tucker *et al.*, 2005), prompting the need to study the ecology of different NSDF successional stages (Quesada *et al.*, 2009). Murphy and Lugo (1986) pointed out that NSDF succession takes place at a slower rate in terms of plant growth but because the canopy of STDF has a relative low tree height and simple vertical structure, they have the potential to recover to a mature state more quickly than do humid forests, and therefore, they are considered more resilient (but see Quesada *et al.*, 2009).

One of the most important NSDF restoration efforts in the neotropics took place in the Santa Rosa National Park, Costa Rica, in 1984, under the initiative of Dr. Daniel Janzen. Restoration of the NSDF of Santa Rosa has been achieved mostly by fire control (Janzen, 1987). As a consequence, the wind-dispersed seeds from neighboring natural forests germinated and seedlings grew to provide shade and habitat for animals, which in turns brought in the seeds of their favorite fruits in their excreta and spittle. The defense of solitary trees in pastures (nuclear trees) from fires was also favorable for natural regeneration, since when the tree got large enough to provide shade for domestic grazing animals and habitat for birds, it attracted seed dispersing animals that brought in the second wave of seeds (Allen, 1988; Janzen, 1987; Castillo *et al.*, 2011).

To highlight the compositional and structural differences between NSDF successional stages, we show results from an ecological study of three successional NSDF stages in Table 2, with information obtained from 26 plots in Santa Rosa, Costa Rica. Measurements were obtained from 26 plots of 0.1 ha each and measuring all trees 10 cm diameter (Kalacska *et al.*, 2004a, b). In general, the results in Table 2 point to a progressive increase in forest structure, tree species richness, and diversity from early to late stages. It is important to notice from Table 2 how pasture land can recover after 15 years of fire protection and become an early secondary forest that provides better habitat and environmental services than degraded pasture land.

Extent and Conservation of NSDF

Approximately 40% of the total world tropical and subtropical regions were once potentially covered by open or closed forest (Murphy and Lugo, 1986, in accordance to the Holdridge Life Zone System; Holdridge, 1967). Of this total potential forest cover, 47% belongs to the dry forest life zone and 53% belongs to the humid forests life zones (i.e., wet, moist, and rain forests).

A recently published study by Portillo-Quintero and Sánchez-Azofeifa (2010) provided new insights into the extent and fragmentation of NSDF in the Americas. This study focused exclusively on NSDF, including satellite imagery selection and classification algorithms that accounted for latitudinal differences in leaf phenology patterns (differences in the date of the range and peak of the dry season and wet season). Their study also focused exclusively on NSDF

Table 2 Structural and functional characteristics of three NSDF successional stages in Santa Rosa National Park, Costa Rica

Trait	NSDF successional forest stage

that fall within the floristic, zoogeographic, and bioclimatic parameters suggested by Olson *et al.* (2001) and by Sánchez-Azofeifa *et al.* (2005b) for North America, Central America, the Caribbean islands, and South America.

From the study of Portillo-Quintero and Sánchez-Azofeifa (2010) several important aspect of NSDF should be discussed.

NSDF Extent

The total extent of NSDF in the Americas as of 2010 was 519,597 km². North and Central American dry forests occupy 203,884 km² of land, this represents 39% of the total extent of all STDF, while South America contains 268,875 km² of NSDF forest representing 51% of the total. The Caribbean islands comprise 46,839 km², which represents 9% of the tropical dry forest remaining. From the analysis of the map in Figure 1 the following information and conclusions can be derived: (a) NSDFs are far from being uniformly distributed through the continent; (b) Mexico has the largest amount of tropical dry forest within its boundaries, comprising 38% of all tropical dry forests; (c) Bolivia and Brazil harbors large portions of NSDF (25% and 17%, respectively); (d) Colombia and Venezuela includes lower percentages (6.5% and 6.2% respectively) of NSDF; (e) together, Mexico, Bolivia, Brazil, Colombia, and Venezuela contain 93% of the tropical dry forests in continental areas; (f) in the Caribbean islands, the majority of dry forests (92%) occur within Cuba and Dominican Republic. Cuba contains 79% (36,996 km²) of all Caribbean islands NSDF representing 7% of the NSDF in the Americas.

NSDF Loss

When comparing the current extent of NSDF in the Americas to its potential extent according to the delineation of the dry forest biome it appears that 66% of the area has already been

converted to other land uses. This value is higher than the world estimate of 48% of NSDF loss made by Hoekstra *et al.* (2005). In North and Central America, 72% of dry forest has disappeared, while South America and the Caribbean islands have lost 60% and 66% of their potential cover, respectively. In continental countries, the magnitude of NSDF conversion ranges from 45% in Bolivia to 95% in Peru, with the next highest conversion in Guatemala with 86%. With the exception of Bolivia, all other continental countries have converted at least 52% of their NSDF cover, and the overall conversion for these countries is an impressive 66%. The five insular countries for which data are available show a magnitude of conversion that ranges from 54% in Jamaica to 78% in Haiti, with an overall conversion of 66%. In sum, this analysis suggests a dramatic rate of conversion, with only 44% of NSDF remaining in the region (Table 3).

It is surprising that given its importance for conservation, no accurate estimates of tropical deforestation exist for NSDF and no distinction or attention is given to it in recent global deforestation assessments where forest extent and deforestation are analyzed as a whole (FAO, 2011). Proper systematic evaluation of NSDF deforestation rates is needed in order to understand regional dynamics of NSDF loss. Costa Rica is probably the only country with accurate estimates of deforestation, with deforestation rates for the period 1986–98 estimated at around 0.2%. Then, for the 1998–2005 time period, deforestation drops close to 0.1%. Costa Rica is most likely the exception to the regional patterns, since much higher rates have been reported for Bolivia and Brazil (Killeen *et al.*, 2007; Steininger *et al.*, 2001).

The causes of deforestation for NSDF are different from those of tropical rain forests. In general, NSDF has been not the last, but the first frontier for economic development policies,

Figure 1 Land-cover map showing the extent and geographical distribution of NSDF derived from MODIS 500-m. Reproduced from Portillo-Quintero C and Sánchez-Azofeifa A (2010) Extent and conservation of tropical dry forests in the Americas. *Biological Conservation* 143(1): 144–155. The map also shows the extent and geographical distribution of seasonally dry forests in tropical and subtropical grassland, shrubland and savanna ecosystems.

and the degradation and deforestation rates in this ecosystem have been greater than for other types of tropical forests (Sánchez-Azofeifa *et al.*, 2005a,b; Portillo-Quintero and Sánchez-Azofeifa, 2010). It is important to separate the effects of continental and insular drivers of deforestation, since they are different. The main driver of change in NSDF is the expansion of the agricultural frontier in Continental America, since these forests are located in areas with excellent soils for agricultural industries and cattle expansion (Sánchez-Azofeifa *et al.*, 2005b; Kalacska *et al.*, 2004a, b; Calvo-Alvarado *et al.*, 2009). Arroyo-Mora *et al.* (2005a,b) and Calvo-Alvarado *et al.* (2009), examining deforestation processes in Guanacaste, Costa Rica, concluded that the expansion of the cattle frontier was the main force driving tropical deforestation in the late 1950s and 1960s, the former contributing to the creation of a highly fragmented landscape. Trejo and Dirzo (2000) studying a NSDF in central Mexico, and later Sanchez-Azofeifa *et al.* (2009) studying deforestation processes in the coastal region of Jalisco and the areas surrounding the Chamela–Cuixmala Biosphere Reserve, arrived at similar conclusions.

Although the forces driving land-use/cover change in NSDF environments appear superficially similar to those for other sites in the tropics, an analysis of drivers of change for

35 Neotropical NSDF ecoregions (Olson *et al.*, 2001) indicates that expansion of the agricultural frontier, cattle ranching, and selective logging emerge as the main dominant drivers in more than 50% of all NSDF sites studied, including both continental and insular sites. Nonetheless, when island and continental sites are analyzed separately, for insular regions the main driving forces are invasion of exotic species, urban sprawl, selective logging, agriculture, tourism development, and road construction. For continental sites, however, the main driving forces are agricultural expansion, cattle ranching, selective logging, urban sprawl, and hunting (Figure 2). When continental and insular drivers are compared, only two drivers of change emerge: selective logging and urban sprawl are common to each region, showing a sharp difference not found previously in the literature. The former has driven us to conclude that the expansion of the agricultural frontier and cattle ranching/grazing were the main forces of land-cover change in this ecosystem.

NSDF Protection

Only 4.5% (23,417 km²) of the total NSDF current extension in the Americas is protected by nature reserves. In South America, 17,816 km² of dry forests are protected. Two

Table 3 Current NSDF forest extent (km²) derived from MODIS 500-m data and area under protected areas at three levels: (a) North, Central, and South American countries; (b) Countries of the Caribbean islands; and (c) Summary of results per subregion

countries, Bolivia and Brazil, jointly contain roughly 64% of all protected NSDF (15,000 km²). Bolivia protects 10,609 km² of NSDF, with approximately 7600 km² being located within the Chiquitano dry forest ecoregion and protected by a single park: the Noel Kempff Mercado National Park. In North and Central America, where 72% of the dry forests have already been lost, only 804 km² (0.4%) are protected. Most of the protection occurs in Mexico and Costa Rica, where a similar

extent is under protection in both countries (about 300 km²). However, the proportion protected relative to their current dry forests extents indicates differences in the relative importance that countries give to the protection of NSDF (See Figure 3). These two countries have large differences in potential and current extent of tropical dry forests, yet Costa Rica protects 15% of its current extent, while Mexico protects only 0.2%. Costa Rica has the highest degree of protection of NSDF in

Figure 3 Percentage of NSDF under Protected Areas. Reproduced from Portillo-Quintero C and Sánchez-Azofeifa A (2010) Extent and conservation of tropical dry forests in the Americas. *Biological Conservation* 143(1): 144–155.

North and Central America, and this might be related to the national priorities placed on conservation. Cuba shows protected areas representing 10.9% and Jamaica about 25% of the NSDF extent. In general, countries in the Caribbean islands show the highest coverage of NSDF under protected status (10.2% of current extent is protected) and countries of North,

Central, and South America protect 3.9% of the forests' extent, this is probably due to the fact that most of their forest cover is in fact dominated by NSDF. However, protection to forests differs qualitatively given that in North, Central, and South America, about 90% of dry forests are protected under the "National Park" status (IUCN Protected Area Category II),

while in the Caribbean islands, 66% are protected under “Sustainable Management areas” (IUCN Protected Area Category VI) and 20% under the “National Park” category.

NSDF Fragmentation

As is apparent in **Figure 1**, NSDF occur in disconnected patches scattered in the landscape, with sizes varying from small fragments (2.5 km²), intermediate fragments (2.5 km² and 10 km²), to large fragments (10 km²). According to *Laurance et al. (2002)* and *Rodríguez et al. (2007a,b)* larger fragments protect better biodiversity and ecosystems functions, while intermediate and small fragments experience higher species extinction and deforestation rates. Given the story of land-cover transformation of NSDF landscapes *Laurance et al. (2002)* observations must be validated for NSDFs regions.

Bolivia has the highest proportion of NSDF in large fragments, followed by Brazil and Mexico (**Figure 4**). The proportions of larger fragments in the majority of countries is 60%, probably because of the way land-use change advances in agricultural lands, leaving patches of NSDF in areas of more difficult access. The highest proportion of small and intermediate fragments is found in countries like Nicaragua, Guatemala, Ecuador, Costa Rica, and Peru. Most Caribbean island countries have a high proportion of NSDF in large fragments (80%) except for Jamaica.

NSDF fragmentation is one of the biggest threats to the protection of biodiversity and ecosystem functions, but it can also be an opportunity for the design and establishment of nature reserves and biological corridors. According to *Balvanera et al. (2011)* agricultural and pastoral goods obtained by removing NSDF are their most commonly recognized ecosystem service, but NSDF also contribute to human well-being through a wide variety of services; including the regulation of a number of processes such as soil fertility, erosion, water cycling, climate, pollination, pests, disease control, invasion by exotic species, and buffering of impacts of extreme meteorological events, as well as many cultural services. Until now, in NSDF landscapes, agricultural production has been favored at the cost of losing most of the other services they provide, probably irreversibly.

Good management strategies of fragmented NSDF landscapes must recognize and recover traditional ethnobotanical information and use of local plant species. *Peters (2011)* indicated that local and indigenous traditional communities in Brazil have learned the properties, uses, and ecological requirements of hundreds of native species from NSDFs. For example, 80% of the species in Pernambuco, Brazil, have been shown to have local uses (*Albuquerque et al., 2005*), more than 400 species have medicinal use in northeastern Brazil (*Victor, 1990*), and more than 176 species are used for food alone in Tarahumara, Chihuahua, Mexico (*Bye, 1989*). *Chazdon et al. (2011)* showed that agricultural landscapes in NSDF regions support a considerable proportion of the original biodiversity but fewer species than found in intact forest. Further research is needed in order to assess the diversity of NSDF species that survive and thrive using the resources available in agricultural areas.

NSDF in Tropical and Subtropical Grasslands, Savannas and Shrublands

Regarding deciduous forest vegetation outside the strict NSDF bioclimatic range, **Figure 1** (from *Portillo-Quintero and Sánchez-Azofeifa, 2010*) shows the extent and distribution of tropical and subtropical forests within important associated savanna, grassland, and shrubland ecosystems. These ecosystems are: the Chaco dry forests, Caatinga, Cerrado, the Llanos, the Beni Savannas, and the Campos Rupestres Savannas. These ecosystems are considered areas where NSDF species could potentially occur (*Miles et al., 2006*).

Results show that the total extent of forests in grassland, shrubland, and savanna ecosystems is 1,069,692 km², which doubles the extent of NSDF. The Dry Chaco comprises 41% of this total; the Caatinga and Cerrado both have very similar extent of forest vegetation, each of them representing about 22% of the total forests; the Llanos and Beni savannas are mostly represented by gallery forests and submontane forests encompassing 9.67% and 4%, respectively; and the Campos Rupestres savannas represents 1% of the total amount of forest in these ecosystems.

In the shrublands and savanna ecosystems, 35,820 km² of forests are under legal protection representing 3.3% of the total extent. The Dry Chaco and the Cerrado woodlands show the largest extent under protection with 13,310 km² and 11,635 km² protected, respectively, followed by the 5446 km² of forests protected in the Llanos ecosystems. The degree of protection is rather similar across ecosystems, although the Llanos and the Campos Rupestres savanna ecoregions have a slightly higher degree of protection. Approximately 90% of these protected forests exist under the “National Park” category status.

The Dry Chaco region contains most of its forest extent in large fragments (**Figure 4**). Caatinga ecosystems are more scattered and fragmented, although a significant proportion still remains as large fragments. A similar pattern is detected along the Cerrado, Beni Savanna, the Llanos, and the Campos Rupestres savanna ecosystems.

Fires and NSDF Land-Cover Change

Although the presence of fires is not considered a major driver in the evolutionary history of part of NSDF, it is considered one of the main factors driving land-cover change in this ecosystem (*Otterstrom, 2006*). Fire in tropical regions is generally considered a landscape-level disturbance that impoverishes ecosystems while it serves as an important element in the human domination of the landscape (*Ehrlich et al., 1997*). *Di Bella et al., (2006)* found that the Neotropical ecosystem that is most affected by the occurrence of fires is NSDF, a fact that was later confirmed by *Wright et al. (2007)*. Given that the majority of the population in the Neotropics lives within the dry forest ecosystem in a matrix of high-intensity agriculture (*Fajardo et al., 2005*), it is expected that fire occurrence will be higher here than in other tropical ecosystems.

In general, fires in tropical dry forests are initiated by farmers, either aiming to control pasture lands at the end of the dry season or as a slash-and-burn technique after clear-cutting, although the latter practice rather than the former is more used

Figure 4 Percentage of NSDF under three levels of fragmentation for countries in North, Central, and South America, the Caribbean and within shrub land and savannas ecosystems. Reproduced from Portillo-Quintero C and Sánchez-Azofeifa A (2010) Extent and conservation of tropical dry forests in the Americas. *Biological Conservation* 143(1): 144–155.

in tropical dry forest environments. Fire control, in fact, is considered to be the most important achievement in the restoration of tropical dry forests at the Santa Rosa National Park after other significant initiatives for forest restoration failed. Unfortunately, our current knowledge of fire's impact on NSDF and their long-term resilience is limited (Otterstrom *et al.*, 2006), and additional work is necessary to better understand the long-term effects of this land-cover change driver.

Climate Change and NSDF

According to the thorough analysis recently carried out by Meir and Pennington (2011) of the possible consequences of climate change on NSDF using a Dynamic Global Vegetation Model (DGVM), the estimated warming rates for NSDF regions are consistent with, or slightly above, the global predicted means of approximately 2–4 °C warming by 2100.

However, the scenarios for regional alterations of rainfall are uncertain and there is no clear global pattern emerging so far from the IPCC (2007). The most recent Intergovernmental Panel on Climate Change (IPCC) examination of the twenty-first century hydrological cycle (Bates *et al.*, 2008) indicates that a 5–15% reduction in soil moisture availability is expected by the late twenty-first century across much of tropical Latin America. These results have also been confirmed by other studies in Amazonia (Timmermann, 1999; Cox *et al.*, 2008; Malhi *et al.*, 2008), but not for tropical dry forests. Other alterations to key climate variables, such as changes in radiation flux caused by differences in cloud cover, are thought to impact primary production (Mercado *et al.*, 2009) and may also influence tree reproduction (Wright *et al.*, 1999). These two effects could be important in seasonal tropical dry forest regions with very short growing seasons. Land-use change impacts are likely to exacerbate the effects of climatic warming, and this may be especially true for NSDF, given that they are mostly already highly disturbed and fragmented.

Although the findings above suggest an increased frequency of extreme events in NSDF at seasonal and longer timescales, predictions about their future status are uncertain for a number of reasons. First, climate models differ considerably in their predictions about rainfall change, the main controller of this system. Furthermore, major grid modeling efforts, and IPCC predictions fail to cover areas associated with NSDFs. Second, the present capacity to model vegetation response cannot fully capture even the information that we already have about the physiological responses of the many constituent species of these systems (Mooney, 2011). Much emphasis had been placed on the impacts of climate change on tropical rain forest, whereas less effort has been made on NSDF (Meir and Pennington, 2011).

Management Aspects of NSDF

An issue that deserves better understanding is the transformation of tropical forests through forest management practices that pursue the sustainable harvesting of timber from natural forests (Sheil and Van Heist, 2000; Quesada *et al.*, 2009). The main argument is that forest logging and silvicultural practices are extrinsic forest disturbances similar in size and intensity to intrinsic natural disturbances such as tree falls (e.g., Skorupa and Kasenene, 1984). Such management practices propose that natural regeneration and gap forest dynamics can be applied to the sustainable management of tropical forests (e.g., Brokaw, 1987; Denslow, 1987; Brandani *et al.*, 1988). Some of the main ecological issues that question these forest management practices are: (1) natural tree falls occur because of dead, hollow, or vulnerable trees and hence forest management implies extra forest disturbance (Uhl and Guimarães-Vieira, 1989; Barrantes *et al.*, 1999; Putz *et al.*, 2008); (2) harvested forest gaps are generally larger than natural gaps favoring the regeneration of pioneer and sometimes exotic invasive species, which in turn simplify and homogenize the forest composition and structure (Barrantes *et al.*, 1999; Costa and Magnusson, 2003; Putz *et al.*, 2008); (3) removal of larger trees will negatively affect subsequent regeneration due to loss of fruit and seed sources

(Barrantes *et al.*, 1999; Costa *et al.*, 2002; Lobo *et al.*, 2007); (4) forest management will negatively affect the role of many animal species in pollination and seed dispersal that is often species specific and difficult to replace; and (5) knowledge of the reproductive attributes of timber tree species is surprisingly limited (Barrantes *et al.*, 1999; Quesada and Stoner, 2004). Hence TSDF ecological research directed to generate additional information along these lines will be important to help resolve the many technical uncertainties in surrounding sustainable forest management and habitat maintenance.

Rainforest Loss and Change

Karndeo D Singh, Academy of Forests and Environmental Sciences, New Delhi, India

Glossary

Change matrices A way to relate area of land-use classes at the beginning with that at the end of a period. From such matrices, it is possible to follow the exact path of change viz. how much land was transferred from a given use to other uses, how much came into that use, and what remained unchanged during the period.

Deforestation The change from forest to other land uses such as agriculture or ranching; or depletion of forest crown cover to less than 10% density. Because shifting cultivation involves a change of land use, it is considered deforestation.

Forest change processes A collective term for all activities on the forest land which affect the stand or site and, in particular, the biological diversity. These processes include

forest exploitation, forest fragmentation, and establishment of new plantations.

Historic rainforest All land areas with a potential to support the tropical rainforest as determined by the climatic and physiographic conditions whether currently forested or not. The concept is interesting because it provides a baseline to calculate the rainforest loss in a country or region over a historic period.

Rainforest formation In the present context, the tropical rainforest formation covers forests areas occurring approximately within a latitudinal belt of 10° on either side of the equator. It may be noted that temperate and subtropical zones have forest formations structurally similar, but biologically not as diverse as the tropical rainforest.

Assessment Techniques

The methods for global forest assessment, of which Rain Forest Assessment forms a part, can be grouped into two broad classes: (1) those based on aggregation of existing country data; and (2) new surveys using remote sensing images. The United Nations Food and Agriculture Organization (FAO) is the Agency responsible for reporting on the subject. In addition, the European Union TREES Programme at ISPRA, Italy, undertakes research studies with a focus on the tropical rainforest worldwide (Achard *et al.*, 2002).

The FAO started global forest assessment in 1948 using a questionnaire approach. After publishing four reports on a 5-year cycle, the global assessment was discontinued in 1963, apparently due to poor response and inconsistent information received from the developing countries. The growing concern about the fate of forests in general and tropical forests in particular, expressed at the Stockholm Conference on Human Environment in 1972, led to initiation of the FAO/UNEP Tropical Forest Resources Assessment with the objective of providing reliable forest area and changes information for the tropical countries, with 1980 as the reference year. The assessment was conducted centrally at FAO HQ Rome by a team of experts under the technical guidance of FAO Forestry Department using reliable country information. The project estimated tropical forest area at the end of 1980 to be 1935 million ha and the annual rate of deforestation during 1980–1985 at 11.3 million ha (FAO, 1982). The news served as a wake-up call to the international community to start action for conservation and sustainable management of tropical forests.

Responding to international concerns, the FAO strengthened its programme on forest resources assessment during the eighties and carried out a number of benchmark activities including: (1) Global Forest Resources Assessment with 1990 as the reference year (FRA 1990); (2) a statistically planned multidecade survey of tropical forests using remote sensing; (3) eco-floristic zoning of

the tropical regions; and (4) tropical forest cover mapping. During the nineties, the FAO continued and improved on the FRA 1990 approaches and extended the coverage of the ecological zone and forest cover maps worldwide. A brief description of the FRA 1990 methods, with special reference to tropical countries will be given as they form the main source of information presented in this report (FAO, 1993, 1996).

Model-Based Assessment

The main steps were as follows:

1. The existing forest resources information on countries (both historic and current at a subnational level) was reviewed and entered in a database called Forest Resources Information System (FORIS). All subsequent observations for the area were to be added to the database as a part of time series information, which would include, besides area, volume/biomass, forest management status, forest utilization, and socio-economic data. FORIS also included subnational level demographic data since 1960 and the ecological zone information.
2. A model was developed for estimating forest cover on standard dates and making projections using time series of forest cover and demographic data and ecological zone information, all at a subnational level.
3. Based on the model equations, forest area and rate of change for various time periods were estimated at the subnational level; estimates were aggregated at the national, regional, and global levels.

Multidecade Remote Sensing Survey

The sample survey of forests in the tropics was designed using multidecade high-resolution satellite images, close to years 1980

and 1990, to estimate forest changes on a reliable basis. The tropical region was divided into 10 geographic and three forest cover strata using the forest cover and ecological zone maps. In all 117 satellite images, each covering approximately 3 million ha, were randomly selected and distributed to various strata. The study, covering nearly 10% of the area of the tropics, was conducted in a very systematic manner under a controlled environment. The two images at each sample site were of comparable quality, taken during the same season and interpreted by the same person under a central quality control. The interdependent image-interpretation procedure enabled assessment of changes with a much lower standard error compared to the independent interpretation of the two images.

The Historic Rainforest Area

Rainforest is the natural vegetation of the equatorial zone. It is associated with a very uniform temperature throughout the year (26–28 °C) and wet conditions with precipitation exceeding evaporation at least for 10 months. The historic distribution of rainforests, as described in Singh (1974), is as follows:

South and Central America: The Amazon basin extending west to the lower slopes of the Andes, east to the coast of Guyanas, south to the Gran Chaco, and north along the eastern side of Central America. Africa: The Congo basin (mainly Zaire and Congo), Gabon, and Cameroon. It extends westward into Nigeria, Ghana, Ivory Coast, Liberia, and Guinea. On the eastern side it extends to Uganda. Asia: mainly Southeast Asia, including the Malay Peninsula, the islands of Sumatra, Borneo, Sulawesi and New Guinea, part of India, Sri Lanka, Burma, Thailand, and the Philippines.

Although climate in the rainforest regions is relatively uniform, there are local variations caused by changes in soil, topography, and geology. These site variations give rise to a corresponding change in vegetation forms. Some typical forest formations in the equatorial zone are the following: The rainforest proper (also called climax rainforest) usually occurs on well-drained soils and below elevations of 500–800 m. This is generally what the common person means when he or she talks of the rainforest. Other types are mangrove forest, swamp forest, periodically flooded forest, riparian forest, hill forest (usually at altitudes higher than 800–1000 m), forest on tropical podzols (a soil type), and forests on coastal sand.

Ecological studies show evidence of striking similarities of vegetation characteristics among the rainforest formations across continents even though they occur in widely separated areas. According to Richards (1952), they are composed of plant species with comparable characteristics and great similarity in their spatial arrangement, life form, and physiognomy. The fundamental pattern of structure is thus the same through the whole extent of the rainforest.

FRA 1990, in close cooperation with the Laboratoire d'écologie Terrestre in Toulouse, France, and member countries compiled the geo-referenced Eco-floristic Zone Map of the tropics, showing boundaries of the potential vegetation types occurring in the tropics (including the rainforest) to provide a basis for estimating the associated areas (FAO, 1989). According to this map, the potential area of the lowland rainforest worldwide is 935 million ha, with 127 million ha

(13.5%) in Africa, 308 million ha (33.0%) in Asia, and 500 million ha (53.5%) in South America. South China and Australia also have small areas of tropical rainforests that are not included in the previous total.

Eco-Floristic Zone Concept

The following model describes the eco-floristic zone mapping procedure used by FAO:

$$Z = f(V, C, P, S|L)$$

where f is the zoning procedure (a rule, classification system, look up Table, etc.) to assign Ecological Zone Values (Z) to land units (L) of a country, region or the world, based on characteristics of natural vegetation (V), climate (C), physiography (P), and soil (S). Climatic criteria are used at a global level of classification; physiographic variables at the regional level; and soil characteristics at the country level of classification.

The Current Rainforest Area and the Rate of Loss

Model-Based Assessment

According to model assessment, the pan-tropical rainforest area at the turn of the Millennium was 680 million ha with the following distribution: Africa 81 million ha, Asia 159 million ha, and South America 440 million ha (see Table 1). Compared to the potential, the still remaining rainforest was 73% of the total and the rate of loss during 1990–2000 was 39 million ha with the following distribution: Africa 5 million ha, Asia 19 million ha, and South America 15 million ha, showing that Asia was losing rainforest at the fastest rate.

Using multivariate data available in FORIS, a time series analysis of rainforest losses since 1960 was carried out. The area loss on a pan-tropical basis during 1960–2000 was 160 million ha, compared to 220 million ha prior to 1960, bringing out the fact that most of the rainforest loss had occurred during the post-1960 period (see Table 2).

Findings of FRA 1990 Remote Sensing Survey

FRA 1990 made a pioneering effort to provide information on the state of forests in the tropics to international community on a continuing and reliable basis. Table 3 summarizes the main findings of the survey on rainforest changes during 1980–1990 grouped into two broad categories: (1) deforestation; and (2) forest degradation. The former refers to outright change from forests to nonforest land uses; and the latter is concerned with changes within the areas classified as forests. A more detailed analysis of changes will be presented later.

Two conclusions are obvious from the findings presented: (1) forest degradation was more wide spread and affecting 36.5 million ha forest area than deforestation, viz. 23.4 million ha. Added together they had altered natural vegetation forms in 60 million ha of the rainforest area. (2) Biological diversity in rainforests of Asia is most threatened on account of a very high rate of deforestation (in % terms) and an equally very high rate of forest degradation.

Table 1 Distribution of historic and current rainforest areas by region

Region	Historic rainforest area Million ha	Current rainforest		
		Area at end 2000		Loss during (1990–2000) Million ha
		Million ha	(%) of the potential

Findings of FRA 2000 Remote Sensing Survey

The FRA 2000 Remote Sensing Survey interpreted images of 1980, 1990, and 2000 on the same sites as FRA 1990 and used an identical statistical design. This makes the initiative of great value in two different ways: (1) to make comparison with results of FRA 1990; and (2) to provide an indication of changes in the rate of deforestation. With regards to the first point, it was found that the results of the two surveys are very close. The pan-tropical estimate of the total forest area by FRA 1990 and FRA 2000 are, respectively, 1656 and 1671 million ha (difference of only 1%); the regional estimates differ by less than 5%; the pan-tropical deforestation rates differ by 10%; and regional deforestation rates by 20% (FAO 1993, 2002).

The rainforest statistics produced by the two survey rounds, however, cannot be compared in a straight forward manner on account of changes in the definition. FRA 1990 defined rainforest to include areas with rainfall > 2000 mm and dry period in a year not to exceed 2 months; while FRA 2000 included all forests in the class with length of dry period in a year not exceeding 3 months. A careful study of the two definitions leads to the conclusion that the FRA 2000 rainforest definition was broader and included all of the FRA 1990

rainforest (viz. 758 million ha) and some of the erstwhile moist forest areas (viz. 244 million ha), which made a total of 1002 million ha observed in 1980 by FRA 2000. The fact that the two surveys had made use of an identical design, surveyed the same sites on two dates, viz. 1980 and 1990, makes it possible to integrate the two datasets as one to study many interesting questions about on-going changes in the three ecological zones on two dates. Table 4 gives observed values of FRA 2000 and FRA 1990 without brackets and inferred values in brackets.

The following interesting facts emerge from the analysis:

1. The observed deforestation during 1980–1990 in the strictly defined rainforest was 3.1% compared to a very high rate of loss (10.6%) in the adjoining moist forest areas;
2. Deforestation seems to be accelerating in (the strictly defined) rainforest areas as well as the moist forest areas included in FRA 2000.

Interpreting FRA 2000 survey findings, Drigo (2005) observes that the most active fronts of deforestation during 1980–1990 were in the wetter parts of the Moist Zone, characterized by a short dry season; and these hot fronts are getting more intense and they are fast moving toward the wetter cores

Table 4 FRA 1990 and FRA 2000 estimates of rainforest areas (all areas in million ha)

Survey rounds	Current rainforest			Rainforest loss			
	1980	1990	2000	1980–1990		1990–2000	
	Area	Area	Area	Area	%	Area	%
FRA 2000	1002	953	896	49.4	4.9	57	6.0
FRA 1990	758	734	(707)	23.5	3.1	(27.1)	(3.7)
Difference	244	(219)	(180)	25.9	10.6	(29.9)	(13.6)

Source: With permission from FAO.

of the remaining rain forest areas. This acceleration is accompanied by the indication of a possible deceleration of the deforestation rate in the (remaining) Moist Deciduous Forest. Arguably, this shift of the deforestation front toward the wetter zones is the most significant trend revealed by FRA 2000. This inference is collaborated by the fact that the rate of rainforest deforestation estimated by FRA 2000 for 1990–2000 shows an increase from 49.4 million ha in 1980–1990 to 56.6 million ha in 1990–2000 (FAO, 2002).

Taking into account all information sources, the remaining rainforest area at the end of 2000 is estimated at 900 million ha following the broader FRA 2000 definition; and at 700 million ha following the stricter FRA 1990 classification. The corresponding decadal losses during 1990–2000 are, respectively, 57 and 27 million ha. Notice also needs to be taken of the acceleration observed in the deforestation rates in the rainforest and the adjoining moist forests during 1990–2000.

Evaluation of the Model and Remote Sensing Survey Methods

It may be noted that data inputs for the model in most cases are country interpreted forest area information based on wall-to-wall remote sensing, local knowledge and ground control, more intensive than possible in global studies. In contrast, the pan-tropical sample survey is based on a statistically planned design meticulously implemented under a central supervision, but it has inherent sampling errors. For the pan-tropical area at 953 million ha in 1990, the standard error was 70 million ha (i.e., about 7.3%); and for the net area change during 1990–2000 at 60 million ha, the standard error was close to 12 million ha (i.e., about 20%). The model derived estimates at the pan-tropical and regional levels, presented in Table 3, are well within the confidence intervals of the remote sensing survey, but forest change estimates tend to lie on the higher side.

Errors are inherent in estimating forest area changes based on country data, which are subject to additional variations arising from the technology used, interpretation quality, timeliness of data, and classification system. FORIS has built in procedures to minimize the effect of such variations inherent in country data by using expert knowledge on country classification and data collection method; and by estimating forest area changes using time series of information at a subnational level. The model also makes use of additional natural and cultural variables, correlated with forest changes, to reduce error. But the fact remains that the precision of model estimates can be improved only through improvements in the quality of country data through country capacity

building and harmonization of methods used by countries, by FAO.

Information on forest degradation is a very important plus point in favor of the pan-tropical sample survey method, not presently possible in model-based assessments. The precision of sample survey techniques for estimating changes could further be improved by incorporating natural and cultural information at the sample sites in the analytical procedure, as done by the model. Further gains are possible by integrating wall-to-wall information obtained by using coarse resolution satellite data in the sample survey based on high-resolution data.

Types of Changes within the Forest Land

So far the transfer of land from forest to nonforest class has been described. Changes within forest land are of equal if not greater interest from an ecological as well as an economic perspective. However, representative country data on these changes, on a global basis, are lacking. The only source of consistent information at a global/regional level are FAO Remote Sensing Surveys, which provide within forest change information in a matrix form (Table 5). The matrices are ideal for tracking changes but not very easy to read. To give a bird's-eye view of the change information, FRA 1990 developed a pictorial presentation called a flux diagram (see Figure 1), which shows area changes on the *x*-axis and associated average biomass changes on the *y*-axis. Thus, the figure as a whole shows the total biomass change in the form of a rectangle. Such a presentation is easy to read and informative for studies on climate change.

The FAO change matrices have nine rows and nine columns that represent the full range of land use and forest cover changes important for the study of biological diversity and climate change. The transition among the first four classes relates to changes within the forest domain and represents various grades of density or forest cover changes (closed and open), spatial disturbance (fragmented), and temporal disturbance (long fallow). The transition among the next four classes relates to transfers from forest to nonforest domain including shrub, short fallow, other land cover, and water. The last class, plantation, could be in the forest or nonforest domain (e.g., forest or agricultural plantation). The two domains are grouped as one because it is not easy to separate them with certainty on satellite images.

A distinction needs to be made between the long fallow and short fallow categories, both of which are affected by shifting cultivation. The distinction between long and short has been

Table 5 Area transition matrix for the period 1980–1990 for the wet and very moist regions of the tropical world

Classes at year 1980	Classes at year 1990 (million ha)									Total 1980	
	Closed forest	Open forest	Long fallow	Fragmented forest	Shrub	Short fallow	Other land cover	Water	Plantations	Million ha	%
Closed forest	685.36	0.96	5.35	2.32	0.42	9.16	10.11	0.36	3.70	717.74	80.5

made with the purpose of dividing the total area under shifting cultivation into predominantly forested, no matter how much degradation has occurred, and predominantly nonforested (but woody) on the basis of estimated intensity of cultivation or, specifically, of the rotation cycle. This distinction brings some

clarity to the controversy about shifting cultivation which, without further subdivision, is sometimes considered non-forest (i.e., classified as 'other wooded land' according to the FAO-FORIS definition) and sometimes forest (i.e., according to the definition used by some countries).

The information appearing in the flux diagram (Figure 1) clearly shows that most of the changes resulted in outright loss of the rainforest. Of the total loss, about 31% went to permanent agriculture, 45% to short and long fallow (viz. shifting cultivation), 7% to fragmented forest, 3% to open forest, 11% to plantations, and 3% to other land uses. A brief account of the process of land-use changes in the three regions follows (FAO, 1996; Drigo, 2005).

Africa: The dominant form of change is *closed forest* → *short fallow*, which is on account of small-scale subsistence farming, whereby the fertility of the soil is regenerated during fallow periods of a few years, as agronomic additives and fertilizers are inaccessible to poor farmers;

- The sequence *closed forest* → *open forest* → *fragmented forest* → *other land cover* clearly represents the various stages of forest depletion, and is an effect of rural and urban population land use and energy needs.

Asia: Characteristic changes in the region are *closed forest* → *other land cover*; and *closed forest* → *Plantations* (particularly in Indonesia and Malaysia); *closed forest* → *long fallow shifting cultivation*; and *long fallow shifting cultivation* → *short fallow shifting cultivation* (intensification of permanent agriculture on traditional shifting cultivation areas (South and South east continental Asia). The process *long fallow forest class* → *closed forest* is a direct effect of the abandoned cultivation.

South America: The dominant typology is: *closed forest* → *other land cover*, which represents deforestation with the highest possible biodiversity loss resulting mainly from the direct conversion of the original forest to cattle ranching and permanent agriculture. The second most frequent transition, *shrubs* → *other land cover*, represents the large areas of Brazilian *caatinga* (steppe typical of the northeast regions of Brazil) and *cerrado* formations (tree and shrub savanna of south-west and central Brazil) that are being converted to cattle ranching. Some positive changes such as *other land cover* → *short fallow*, *other land cover* → *shrubs* or *other land cover* → *fragmented forests*, which represent regrowth of previously cleared forests.

The outcome of the land-use change, viz. what happened to the deforested land, is a very important determining factor of the biodiversity loss, the impact of change on the functioning of the ecosystem proper and its affect on the adjoining ecosystems including the indigenous population. In particular, changes involving large scale land clearing, tilling of land and introduction of exotic species might have adverse local, regional, and global implications. It may even lead to ecosystem instability in extreme cases. Keeping in view such a likelihood, the driving forces and socio-economic impact of deforestation are briefly presented by region based on a recent report (UNEP, 2009).

In the Congo Basin, the forest loss and degradation is mainly caused by the displacement of people due to war and conflict and the impact of mining activities in previously untouched forest areas particularly along the tributaries of the Congo River, most likely due to population growth and settlement. In the densely populated mountainous regions and high plateaus of western Cameroon and the east of Democratic Republic of Congo, forest regeneration is reported as getting deficient due to the shortening of fallow periods, combined with the conversion of abandoned fields into

pasture. The productive forest areas in the entire Basin, barring protected areas, seem to be under logging contracts.

A main driving force for the rainforest loss in Asia region is cultivation of oil palms. In 2006, two countries, viz. Indonesia and Malaysia, accounted for 85% of the total world production and 88% of global exports. Over the past decade, the area covered by oil palms in Indonesia has quadrupled, covering 4.1 million ha in 2006.

In Papua New Guinea, logging in approximately 80% of the productive forests would be completed by 2020. In Kalimantan, Indonesia, there are reports of protected area being logged with the loss of more than 56% area between 1985 and 2001. The interests of commercial activities such as palm oil plantations or mining often clash with the interests of communities, small farmers, and indigenous people.

In the Amazon region, cattle ranching, Soya cultivation, and commercial logging operations were the main contributing factor to rainforest loss. In Brazil, ranches covered an area of at least 8.4 million ha and accounted for an estimated 70% of deforestation in 2007 with an average size of 24,000 ha, some ranches could be as large as 560,000 ha. The rising demand for Soya in the world trade has been also an important factor. Brazil is presently the world's second biggest Soya bean producer, accounting for 23% of the global total and about 22 million ha of land under the crop, mostly in the south-eastern part of the country.

Implications for Biological Diversity

The large scale land clearing and human settlements, ongoing in all the rainforest regions, are bound to cause radical and even irreversible changes in the natural (primeval) ecosystem including the indigenous people, whose cultural identity is strongly correlated with the biological diversity. Efforts need to be made to arrest the process of biological diversity loss by careful conservation planning ensuring that the number of individuals per species in the ecosystem does not fall below a critical limit in all forest types, where the species occurs (Singh, 2005). There is an urgent need for nationwide continuous inventory of forests and wild animals. This is a very challenging task to monitor, as not only the number of species in rainforests is large, but also their occurrence is rare, calling for a special effort for getting reliable species identification.

Deforestation and Species Richness Loss

FRA 1990 provides a method for estimating risks of species richness loss associated with deforestation in the form of an index, using the well-known phenomenon of increase of species number with increasing forest area and conversely, loss of species richness with decrease in forest area. Details of concept and methodology for estimating the index are presented in FAO (1993).

Table 6 provides values of indices by region. The risk of species richness loss is the highest in Asia region. This fact is confirmed by findings of FAO model studies and Remote Sensing Surveys presented earlier. This region by the end of the Millennium had lost about 48% of its historic rainforest area

Table 6 Risk of species richness loss associated with deforestation (refers to angiosperm species only)

Region	Forest area (million ha)		Deforestation (million ha) 1981–1990	Species richness (number) 1990	Risk of species richness loss (%) 1980–1990
	1980	1990			
Africa	91	86	5	30,700	2.0
Asia	200	178	22	40,400	4.3
South America	471	455	16	57,900	1.6

Source: With permission from FAO.

and had the highest rate of deforestation (in % terms) and highest rate of forest degradation (in absolute terms). The area logged and the intensity of logging was also high compared to other two regions. Only Indonesia still had some large tracts of rainforests left; the other countries had only small areas in a highly fragmented forms. Immediate and effective conservation measures are needed in this region.

Africa initially had a small share of the world's rainforest and lost nearly 36% of the area by the Millennium end. In particular, the West Africa had undergone a very high loss of the historic rainforest area, with the remaining forests occurring in a highly fragmented manner like islands in a sea of forest fallow (FAO, 1993). The ongoing changes in the central African region were observed to be relatively slow during 1980–1990. However, the recent flux of population at the border of Zaire and Rwanda must have affected the rate of loss and biological diversity, but this effect is not yet known. Second, the ongoing forest area changes in Africa are from closed forest to short fallow, which is an extensive and destructive form of land-use change from the biological diversity perspective. The pattern of transfer is different from that of South America or Asia, where the land-use change is more planned and intensive. With a high rate of population growth, such land-use changes are a cause of concern for forestry and biological diversity conservation perspective.

The land-use changes in South America and the Amazon, in particular, are of more recent origin compared to those in Asia and Africa. The total area of the rainforest is still very high (viz. nearly 88%) and the total area lost is relatively small. However, a state-wise distribution of the remaining forest cover and the rate of deforestation provide a different view. Only the states of Amazonas, Roraima, and Amapá have large tracts of inaccessible forests; other states, such as Maranhão, Tocantins, Pará, Mato Grosso, Rondonia, and Acre, are undergoing larger than average forest area changes per capita compared to other regions of the world.

Loss of Cultural Diversity Associated with Deforestation

According to Dobzhansky (1964), there is intricate mutual relationship among inhabitants (of an ecosystem) which makes them attuned (coadapted) to the manifold reciprocal dependencies. Natural selection becomes a creative process and leads to emergence of new modes of life with more advanced types of organization. An ecosystem could thus be seen, as a higher level, interspecies organization opening possibilities for progressive evolution and responding to the pressure of natural selection in an effective manner. This bond or web of life falls apart with increasing human intervention in the ecosystem from outside.

Rainforests in all the three regions abound in cultural diversity. Any form of forest changes affects them directly, deforestation in particular. The following account of cultural richness in the three rainforest regions is based on UNEP (2009).

The Central African forests are the home of 30 million people, coming from 150 different ethnic groups. A majority of these groups are indigenous and include the Pygmies, as well as many groups of Bantu origin that have been forest dwellers for more than 1000 years and have intermixed with Pygmy, Ubangi, and Sudanic populations.

Indonesia, with rainforest area of 94 million ha, is home of 500 ethnic groups speaking more than 600 languages. This diversity is accepted as a cultural asset, which is reflected in the national slogan, *Bhinneka Tunggal Ika*, unity in diversity. These groups are widely distributed in islands with difficult access and need to be empowered to protect, manage, and share equitable benefits from harvesting operations and land-use changes.

In the Amazon Rainforests, there are more than 200 major indigenous groups, each with their own cultural heritage and language. This shows that like the flora and fauna, the cultural diversity in all the three regions is also very high, which needs to be taken into account in planning of land-use changes.

Loss of Ecosystem Resilience

There is much empirical evidence, and some theoretical support, for the notion that as diversity increases in forests, so does their robustness or resilience in terms of their ability to withstand external stresses. Agents that can cause these changes include wildfire, severe storms, or outbreaks of pests and disease. These events are an integral part of the dynamics referred to as disturbance events (Singh, 2005). The maintenance and monitoring of biodiversity at stand, species and ecosystem levels should be an integral part of forest management and conservation. The strategy should encompass protected as well as sustainable managed forest areas over the entire geographic range of a country/region.

According to Wilson (2000), if habitat destruction were to continue in forests and coral reef alone, half of the species of plant and animal diversity would be gone by the end of the twenty-first century.

The time series data on forest cover and population changes, collected by the FRA 1990 project from all regions of the tropics, show a more rapid forest area loss with an increase of the population pressure in the rainforest region compared to other ecological zones (Figure 2). The rainforest, per unit area, is also the most biodiverse. The two facts imply a larger loss of diversity by human settlement and hence the need for a

Figure 2 Illustration of model curves for different ecological zones.

long-term perspective and care in planning of land use and forestry changes in the tropical rainforest zone.

Glossary

Area of endemism An area recognized by congruent distributions of two or more groups of organisms.

Biogeography The study of the distributions of organisms on Earth and why the patterns exist.

Cladistic biogeography The combination of cladistics (phylogenetic systematics) with vicariance biogeography. A method that searches for patterns of relationship among areas of endemism.

Cladistics (phylogenetic systematics) A method of phylogeny reconstruction concerned with branching patterns. Sister group relationships are hypothesized on the basis of shared derived, or synapomorphic, characters.

Components Elements of groups of areas, or taxa, as determined by the branching pattern of a cladogram. For example, in a group comprising three taxa A, B, and C, when B is more closely related to C, there are two components, an ABC component and a BC component.

Dispersal The movement, or spread, of an organism from one area to another independent from other organisms and of historical events that change the natural distribution of the organism (see [Figure 1](#)).

Ecological biogeography Spatial patterns of organisms considered in terms of their interactions with other organisms and the environment.

Endemic A taxon, or group of taxa, restricted to a proscribed area and found nowhere else on Earth.

Historical biogeography Spatial patterns of organisms interpreted in terms of their concordance to patterns of Earth history.

Panbiogeography The examination of distributions and relationships on a worldwide scale; term introduced by [Croizat \(1964\)](#).

Plate tectonics (including continental drift) The theory that the Earth's crust is composed of plates that move relative to each other through seafloor spreading and subduction. As continents are found on plates, continental drift is one result of this movement.

Vicariance The existence of closely related taxa or biota in separate, disjunct areas, which have been separated by the formation of a natural barrier (vicariance event).

Vicariance event The splitting of a taxon or biota into two or more geographical subdivisions by the formation of natural barriers, e.g., mountain building, glaciation, or stream capture (see [Figure 1](#)).

Historical Biogeography

Biogeography means many different things to biologists and geographers of different persuasions depending on their outlooks and purposes of enquiry. It has been clearly noticed and well documented through accumulation of systematic distribution data for most groups of organisms over the past two centuries of global exploration that there are many organisms that exhibit particular distribution patterns on Earth. In efforts to interpret these patterns, biogeographers pose the question: "What lives where and why?" The usual answers invoke either ecological or historical explanations, or a combination of both (Nelson and Platnick, 1981; [Craw et al., 1999](#); Humphries and Parenti, 1999).

For the most part ecological biogeographers classify distribution patterns as communities in a general hierarchy of organization. Populations and species live in habitats that belong to different land classes in ecosystems within biomes. Few would dispute that many similarities of climate, topography, habitat, and landscape exist between, for example, the rain forests of South America, Africa, and Southeast Asia, but, when examined closely, the resident organisms in each rain forest are specifically and generically quite different. Similar species in similar ecological niches belong to phylogenetically disparate taxa that have particular phylogenetic

and distribution histories that have occurred through geological time. Historical biogeographers focus on the older developments of global biotas in an effort to study the history of the Earth rather than relatively more recent events such as short-term species interactions and recent perturbations in distribution due to climatic changes.

Data for historical biogeography come from comparative biologists and systematists who include distribution information in their monographs and revisions. A major synthesis is found in the works of Croizat, especially in *Space, Time, Form: The Biological Synthesis* (1964; see [Craw et al., 1999](#)). Croizat considered geological events and changes in Earth history and the "form-making" of species as two parts of a continuous historical process. To him, evolution of the Earth and the evolution of organisms are part and parcel of one series of historical events. Recently, greater attention has been given to these ideas, kindled by the general acceptance of plate tectonics and the notion that the continents are continually reshaped and changing in their spatial geometry (see [Craw et al., 1999](#)). At the same time, there has been a widening interest in the use of cladistics for systematic investigation of organisms ([Hennig, 1966](#)). Today, cladistics is considered as the primary means of reconstructing the relationships of organisms. Comparing different groups of organisms sharing similar distribution patterns and occupying similar areas of

endemism with historical patterns in geology and Earth history allows biogeographers to provide retrodictive hypotheses of divergence and explanations of past and present diversity of organisms (Humphries and Parenti, 1999).

Vicariance, Dispersal, and Extinction

Particular species are endemic to certain areas today either because their ancestors originated there and their descendents have survived to the present day or because the ancestors occurred elsewhere and later some of the descendents dispersed into new areas. Such a difference invokes two, very different, historical explanations which in a shorthand way are described as vicariance or dispersal modes of diversification. In a vicariance explanation, an ancestral species (Figure 1a, 1) divides into two separate populations when a physical barrier is formed across the population such that neither of the two new populations can cross over the barrier (Figure 1a, 2). With time, the two separated populations evolve into two closely related species, shown here as black-and-white ovals (Figure 1a, 3). In a dispersal explanation, the range of one species is already bounded at least in one direction by a barrier (Figure 1b, 1), which is later crossed by some members of the population (Figure 1b, 2). If the organisms of the new population survive, successfully interbreed, and yet remain isolated from the “ancestral” population, they eventually evolve into a different species (Figure 1b, 3). Thus, in the vicariance explanation the appearance of the barrier is seen as the cause of the disjunction of the two species, whereas in the dispersal explanation the barrier is considered to be older than the disjunction.

Examples of Vicariance and Dispersal

By Victorian times and the emergence of evolutionary theory, it was clear that the distinction of dispersal and vicariance explanations was emerging. As described by Nelson and Platnick (1984), the English botanist Joseph Hooker (1817–1911) provided perhaps the earliest coherent vicariance explanations of plant distributions. Hooker studied the plants of the Southern Hemisphere in South Africa, Australia, southern South America, and New Zealand and concluded that their pattern of distribution suggested a former, more

extensive flora, which had broken up by geological and climatic causes. Hooker compared the southern floras with those of the Northern Hemisphere and also concluded that the various southern floras were more closely related to each other than any were to the floras of the Northern Hemisphere. As a consequence, he also boldly concluded that divergence of the northern and southern floras must have occurred before the fragmentation of the southern floras. His vicariance hypothesis considered that initially a worldwide flora was first subdivided by a barrier into the northern and southern floras and then the latter were further subdivided by expanses of ocean—barriers severing once continuous floras that no longer exist today.

Nelson and Platnick (1984) compared Hooker’s views with fellow Englishman Alfred Russell Wallace, another great biologist of the late nineteenth century. Wallace disagreed entirely with Hooker’s hypothesis. In 1876, he said that the north and south division of biotas was not a vicariance pattern but represented the fact that

“... the northern continents are the seat and birthplace of all higher forms of life, while the southern continents have derived for the greater part, if not the whole, from the north; ... it implies the erroneous conclusion that chief southern lands—Australia and South America—are more closely related to each other than to the northern continent.”

At that time the prevailing geological theory was one of fixed continents and slow, gradual changes in both Earth history and biogeographical developments. Hooker saw a close connection between cause and effect and said that the basic pattern of relationships divided the northern from the southern taxa, and the pattern was explained by vicariance events. Wallace, heavily influenced by Darwinian selection theory on the other hand, did not see a necessary connection between distribution and Earth history. For him, the basic pattern was east–west and the pattern was explained by dispersal from northern centers of origin.

Plate Tectonics

It has become clear that the nineteenth century was characterized by the dominance of British Empire and European colonialism throughout the world. It was clear that the “higher forms of [human] life” inhabiting the north were invading and dominating elsewhere, particularly the countries of the Southern Hemisphere (Nelson and Platnick, 1984). It was no accident that the “favored races” were of northern origin as indicated in the title of Darwin’s (1859) famous book: *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggles for Life*. Although throughout his life his ideas changed, Wallace’s earlier views on biogeography were part of Darwinian orthodoxy (Nelson and Platnick, 1984). Many groups of animals and plants were seen created in “centers of origin” in the Northern Hemisphere to then disperse and colonize other parts of the globe. Following the central dogma of Darwinism, the colonizing organisms were seen as the surviving fittest and superior competitors to all others that lay before them. The less fit southern forms

Figure 1 Vicariance and dispersal explanations: (a) vicariance; (b) dispersal. See text for explanation.

became thrust aside and eventually extinct. This rather fanciful scenario has been repeatedly described in textbooks, even within the 1990s, and is sometimes known as the “monoboreal relict hypothesis” (Nelson and Platnick, 1984).

The origin of taxa from “centers of origin” and by dispersal to other areas is heavily entrenched in biogeographic literature, an idea that goes back to the Age of Reason in the eighteenth century. For example, Linnaeus believed that if the Earth was changing, with continents growing in size, and that the process had operated in the past

“... the continent in the first ages of the world lay immersed under the sea, except a single island in the midst of this immense ocean; where all animals lived commodiously, and all vegetables were produced in the greatest luxuriance ...” (translated from Linnaeus, 1781, p. 77; see Nelson and Platnick, 1980).

Linnaeus knew that different organisms had particular lifestyles and he suggested that the “center of origin” must have been a primordial island in the Tropics and “bore a very lofty mountain” inhabited at different altitudes by species with different ecological requirements. As new land emerged beyond this island and as the seas receded, the resident organisms migrated by various means to colonize the new parts with suitably similar ecological conditions (Nelson and Platnick, 1980). Embedded deeply within these comments are two important ideas: that species originate and disperse from a “center of origin” and that regularities in distribution are controlled by ecological conditions.

During the nineteenth century adherence to dispersal could be attributed to contemporary geological and geophysical theory. Such a belief allowed only stable continents separated by permanently wide oceans. Biogeographers, such as Hooker, who considered former land connections and favored vicariance explanations, were scorned as being out of line with the prevailing view (Nelson and Platnick, 1984). Even though the late nineteenth century and the first half of the twentieth century produced occasional theories that suggested continents were mobile and forever changing in shape and position through continental drift, mountain building, and erosion, dispersal theories still dominated the literature. It was not until the 1960s that geophysical studies eventually showed that continents and ocean bottoms were not permanent geographical features and that a general acceptance, one of the great paradigm shifts in science, came about. Early theories of continental drift were based on a model of the world that had a fixed diameter and that all of the present-day continents were joined up into one supercontinent, Pangea. During the Jurassic, some 180 million years ago, the supercontinent broke up into two major landmasses, the southern supercontinent, Gondwanaland, and the northern supercontinent, Laurasia. Laurasia contains those areas that have subsequently crystallized out into Europe, North America, and Asia, but exclude the Indian subcontinent. From the Cretaceous onward, the southern end of the world, Gondwanaland, broke up into those areas we now know as Antarctica, Australia, India, Africa, and South America.

The breakup of Gondwanaland lends credence to vicariance biogeography and hence Hooker’s theory. The similarities among floras of the Southern Hemisphere suggest former

land connections. It also revived the theory that Hooker’s hypotheses of north–south connections exist for plants and contradicted Wallace’s theory of east–west connections based on animals. As Nelson and Platnick (1984) asked, how can we determine which hypothesis is correct? Are both theories correct to some degree, or is there another hypothesis that should be erected which subsumes both into one explanation? The interesting point is that if the explanation is a general one, what process caused it and what methods are required to uncover the historical pattern? Paradoxically, through attempts to resolve the relationship between space, form, and time in terms of vicariance and dispersal, including application of track analysis in panbiogeography (Croizat, 1964; Craw *et al.*, 1999) and cladistics in vicariance biogeography (Nelson and Platnick, 1981), it was clear that a more general issue was at stake. This was the question of how to interpret patterns of plant and animal distributions in a systematic way to provide independent theories of biogeography, rather than rely on geophysical and geological theories as prior explanations for present-day distribution of biotas (see Humphries and Parenti, 1999). To give some flavor of the rather fitful debate this idea created, the stages of application of cladistic methods that grew out of vicariance biogeography are briefly described.

Cladistic Methods In Biogeography

The analysis of patterns in cladistic biogeography starts with finding the species or higher taxa that exist in the different biogeographic areas and to discover their relationships. Cladograms, or branching diagrams, are used to express hypotheses of relationship between organisms. An example is shown in Figure 2a, where among the four species, C and D are more closely related to each other than either are to B, and also species B, C, and D are more closely related to each other relative to A. The cladogram specifies two inclusive

Figure 2 (a) Cladogram depicting the relationships between four species. A–D are four recent species, X–Z are hypothetical ancestors, and 1–3 are group-defining characters. (b) Area cladogram showing application of the progression rule to species A and B in South America (SA), C in eastern Australia (EA), and D in New Guinea (NG).

informative groups of species, BCD and CD. Cladograms are produced by the distribution of characters or features shared by the different species or taxa. Thus, in **Figure 2a**, character 3 specifies the group CD, character 2 specifies group BCD, and character 1 specifies ABCD as the overall group. Characters 2 and 3 then specify unique groups that have characters not shared by any other organism. If such features are taken to be present in the ancestors of each group, then the cladogram can be taken as specifying the pattern of evolution or common descent of that group. Seen in this way, the cladogram of **Figure 2a** may be taken to specify that taxa C and D have a unique ancestor Z that is not the ancestor of A or B and also that taxa B, C, and D have an ancestor Y that is not the ancestor of A. CD and BCD are monophyletic groups, compared, for example, with A and D, which is a polyphyletic group, and A and B, which comprise a paraphyletic group.

Cladistics was applied to biogeography in the 1960s at about the same time when theories of plate tectonics and shifting continents were becoming respectable. However, dispersal hypotheses to explain distribution patterns were still in vogue and thus the earliest applications in biogeography used cladograms to determine “centers of origin” of monophyletic groups. The German dipterist Willi Hennig (1966) reasoned that there is a recognizable, close relationship between a species and the space each occupies. He assumed that dispersal patterns are unique for each taxonomic group and that each had an independent history.

The Progression Rule

Central to Hennig’s (1966) method to find a center of origin for a group of taxa from a particular cladogram was the idea that phylogenetically primitive members of a monophyletic group will be found near the center. That is, they are occupied by the species nearest to the basal nodes of cladograms. Within a continuous range of species of a monophyletic group, it was plausible that a series of characters transform and run parallel with distribution in space, such that the youngest members would be on the geographic periphery of the group.

To apply the “progression rule,” one works backward considering the areas in the terminal positions of the cladogram and then gradually working down to the base of the cladogram, assigning distributions to the internal nodes or the common ancestors. If the areas occupied by the descendents do not overlap, they are combined together in assigning the probable distribution of the common ancestor. If they do overlap, the unshared element is eliminated. Consider the four species in **Figure 2b**. Species A and B occur in South America, C occurs in eastern Australia, and species D occurs in New Guinea. Working from the most derived species, C and D, the distributions clearly do not overlap; hence they are added together to give the area for ancestor Z as eastern Australia plus New Guinea. For ancestor Y the descendent taxa do not overlap, with B occurring in South America and ancestor Z in eastern Australia and New Guinea. The two distributions do not overlap so the area for ancestor Y is South America, eastern Australia, and New Guinea. Moving down the cladogram to ancestor X, descendent species A occurs in South America and

ancestor Y in South America, eastern Australia, and New Guinea. The two distributions thus overlap in South America, and eastern Australia and New Guinea are eliminated as the unshared area. Working back up the cladogram, the simplest hypothesis is to consider that South America is common to all three ancestral species, X, Y, and Z, and that species C and D dispersed to eastern Australia and New Guinea from South America. The conclusion from analysis of this biogeographic pattern is that the center of origin for the group is South America.

To demonstrate this early use of cladograms in biogeography, a simple example can be seen in the caddis fly distribution of *Wormaldia* (Ross, 1974; see Humphries and Parenti, 1999). *Wormaldia* and other caddis flies have been a lifelong study of Ross because they occur in almost all freshwater systems throughout the globe, show a high degree of endemism in all areas, and are very speciose. Ross considered the geographical distribution of the nine species of the *Wormaldia kisoensis* complex of caddis flies. Eight species are present in the western Pacific from northwestern Borneo in the south and Japan in the north and one species occurs in the Smoky Mountains of eastern North America (**Figure 3**). The cladogram of phylogenetic relationships is shown diagrammatically in **Figure 4**. Like Hennig, Ross (1974) assumed that the species nearest to the base of the stem of the cladogram denotes the ancestor of the group. He applied also the progression rule to the analysis to determine the center of origin of the group. In *Wormaldia* the most derived species pair occurs in Japan and eastern North America, which led Ross to propose the dispersal hypothesis of origin of the group in the western Pacific and a single dispersal of one species across the Bering straits to North America (**Figures 3 and 4**).

Brundin’s classic studies of chironomid midges (Brundin, 1966) showed that the southern temperate areas of South America, Southern Africa, Tasmania, southeast Australia, and New Zealand are inhabited by 600–700 species. Trans-Antarctic relationships are a recurring phenomenon throughout the group, so by way of an example consider the midges of subfamily Diamesinae, which show a double distribution: two major groups present in both Northern and Southern Hemisphere temperate areas but absent from the Tropics. The largest and most widespread is the relatively generalized tribe Heptagymi, represented by eleven species in Andean South America, two species in southeastern Australia, and five species in New Zealand (**Figure 5**). Its sister group is the relatively more apomorphic and monotypic tribe Lobodiamesini of New Zealand.

The cladogram in **Figure 5** shows that there are a total of 25 terminal taxa in the Southern Hemisphere areas of South America, New Zealand, Australia, and South Africa and three groups in Laurasia. The monotypic genus *Heptagyia* occurs in South America and *Paraheptagyia* has five South American species. According to Brundin, the southeastern Australian subgroup of two species is a younger evolved offshoot of the older South American group including *Heptagyia*. Brundin considered the Australian taxa to have dispersed from Patagonia or east Antarctica at stem 6 by the end of the Paleocene because they have derived characters and because the stem species (indicated by 1, 2, and 4) never occurred in Australia. The other stem (2a) includes the genera *Reissia*, with three

Figure 3 Distribution of the *Wormaldia kisoensis* group of caddis flies. The circle in Japan is *Wormaldia kisoensis*, and that in North America is *Wormaldia mohri*. (Redrawn from Ross HH (1974) *Biological Systematics*. Reading, PA: Addison-Wesley, with permission from CUP.)

species in South America, *Limaya*, with two species in South America, and *Maoridiamesa*, with five species in New Zealand. Brundin (1981) considered that *Maoridiamesa*, on a different stem from the Australian *Paraheptagyia* group, agreed well with plate tectonic theory for an early separation of New Zealand from western Antarctica in the Upper Cretaceous. The fact that *Maoridiamesa* is a comparatively younger, derived offshoot of an older group in South America was, according to Brundin, evidence of long-distance dispersal from South America via west Antarctica to New Zealand of stem species 4a rather than a vicariance event. In other words, Brundin thinks that the *Maoridiamesa* group is younger than the areas in which it occurs.

The progression rule can be interpreted as one particular optimization procedure applied to cladograms. It has problems in the sense that it can specify a different center of origin

when applied to different data. Changes in data occur for a host of different reasons, but largely through the discovery of known taxa in new places, the discovery of new taxa, and reinterpretation of relationships. Patterson (1981) showed that the progression rule was very sensitive to the discovery of new taxa, and particularly fossils. The discovery of fossils simply added more areas to the problem and thus increased the number of possibilities for finding new centers of origin. Thus, for example, if we added two new fossils, V and W, to the example described earlier (see Figures 2 and 6), then the possibility of a center of origin in North America and in turn Europe would alter the interpretation significantly. Patterson considered that for groups of organisms with a significant fossil record, the progression rule is heavily influenced by fossils and this would be especially true in the areas where the best fossils occurred. The progression rule is dependent on the notion that organisms occur in a center of origin. The problem is that when the progression rule is applied to a cladogram, it can always specify a center whether it may, or may not, have occurred. Suppose, for the sake of argument, the species of Figure 6b in Europe, North America, South America, eastern Australia, and New Guinea were caused by the breakup of continents, a vicariance explanation; then the progression rule would provide a spurious hypothesis impossible to test.

Vicariance Biogeography

The problem of interpreting cladograms as dispersal scenarios is the same as treating them as phylogenetic trees rather than as hierarchical classifications to show groups with relatively more inclusive groups of set membership. Such a procedure requires making ad hoc assumptions not based on the information on which they are based. Furthermore, interpreting individual cladograms as having individual

histories leads to certain conceptual difficulties. A crucial one is how do we interpret repetitious distribution patterns? If we have many unrelated taxonomic groups repeating a pattern of distribution between major continents, such as

Figure 7 Four hypothetical groups of organisms showing the same area relationships.

South America, eastern Australia, and New Zealand (Figure 7), it is improbable that the pattern was caused by separate unique dispersal events. This implies that species in each different group separately makes its own way from one continent to the other. A logical and more robust conclusion would be to suggest that at one time, the continents were in contact and that the present-day pattern was due to the breakup of a formerly continuous biota.

The breakthrough in application of cladistic reasoning to biogeography came with the realization that disjunct distributions could occur because of such vicariance events. This is based on the idea that present-day endemic taxa occur in the same areas as their ancestors and the Recent taxa evolved *in situ*. Where dispersal models explain disjunctions by dispersal across pre-existing barriers, vicariance models explain them by the appearance of barriers fragmenting ancestral species ranges (Figure 1). To historical biogeographers what became particularly clear was the important idea that distribution data are insufficient to resolve decisively either dispersal or vicariance as the cause of disjunct distribution patterns.

Platnick and Nelson (1978) argued that one should not worry about the cause of a disjunct distribution pattern between different related areas of endemism but whether or not it conforms to a general pattern of relationships shown by other groups of taxa endemic to the areas occupied. Thus, there is an analogy to the three-taxon statements in systematics as the most basic units for expressing relationships. In biogeography three-area statements are the most basic units for expressing relationships between areas of endemism. The generality of the area cladograms can be examined by comparison with other unrelated taxonomic groups endemic to the relevant areas and corroboration of a particular pattern is equivalent to a general statement for the relative recent ancestry of the biotas under scrutiny. However, there has been a long, drawn out saga of trying to find ways for applying the principles of cladistic biogeography because initial applications of the method (e.g., Rosen, 1976) encountered problems of incongruence between different groups of organisms. Theoretically, it should be possible to connect every area of endemism of the world into one huge general statement of interrelationships. However, our perception of the world is less than perfect for a variety of reasons—extinction, dispersal of widespread taxa, and restricted distributions of taxonomic groups. The significance of these problems can be demonstrated with poeciliid fish in Middle America.

Poeciliid Fish In Middle America

To discover relationships of areas, at least two groups of taxa must be available for the same or similar set of areas. Rosen (1978, 1979) examined two groups of fishes, *Heterandria* and *Xiphophorus* from the Mesoamerican region. Both genera have close relatives elsewhere but each has a monophyletic subgroup inhabiting 11 areas in southern tropical Mexico, south to eastern Honduras in *Xiphophorus*, and further south to eastern Nicaragua in *Heterandria* (Figure 8). Area cladograms

Figure 8 Map to compare the distributions of the species of *Heterandria* (full line) and *Xiphophorus* (broken line). Numbers refer to areas defined by the occurrence of taxa. for the two genera, which indicate areas occupied by particular species, are shown in Figures 9 and 10.

Component Analysis

Cladistic biogeography would be uncomplicated if all groups of organisms were each represented by one taxon in each of the smallest identifiable areas of endemism. This is not the case. Unique patterns may be meaningful and cannot at the same time be incongruent with patterns determined from

Figure 9 Area cladogram for *Heterandria*. The numbers refer to areas denned by the species as shown on the map in Figure 8. (Redrawn from Figure 48 in Rosen DE (1979) Fishes from the uplands and intermontane basins of Guatemala: Revisionary studies and comparative geography. *Bull. Am. Mus. Nat. Hist.* 162: 267–376, with permission from Society of Systematic Biology.)

Figure 10 Area cladogram for *Xiphophorus*. The numbers refer to areas defined by the species as shown on the map in Figure 8. (Redrawn from Figure 49 in Rosen DE (1979) Fishes from the uplands and intermontane basins of Guatemala: Revisionary studies and comparative geography. *Bull. Am. Mus. Nat. Hist.* 162: 267–376, with permission from Society of Systematic Biology.)

By using the assumption that one sequence of historical events can explain the patterns observed in both *Heterandria* and *Xiphophorus* and then using the logic applied for the hypothetical example used for the breakup of Gondwana (Box 1), a single result can be obtained. **Platnick (1981)** noted that if widespread taxa are uninformative, they cannot at the same time be incongruent. We can assume that the information on areas 6 and 9 in *Heterandria* is correct. Thus the incongruent information in the same areas for *Xiphophorus*

Table 1 Informative components (three-item statements) of the three cladograms in **Figure 12** (scored as 0(1,1))

Area	Components expressed as three-item statements				
	1	2	3	4	5
Root	0	0	0	0	0
South Africa (SA)	0	–	–	–	–
New Zealand (NZ)	1	1	1	1	0
Pacific South America (PSA)	1	0	1	0	1
Eastern Australia (EA)	–	1	0	1	1

Figure 12 General-area cladogram for lizards (species of lizards (L1–L3), birds (B1–B3), and fishes (F1–F3)). The acronyms for areas are as in **Figure 11**. The five informative components (1–5) identify area relationships.

(areas 6 or 4–5, but not both, and 9 or 10, but not both) is due either to dispersal or a failure to speciate in response to vicariance events that gave the pattern in *Heterandria*. Taken on their own, widespread taxa are uninformative. However, when considered with other cladograms, informative results are possible. Similarly, “absence” data (e.g., area 3 in *Heterandria* and area 7 in *Xiphophorus*) can never be incongruent with information at hand so unique areas should be placed in terms of whatever pattern exists (i.e., area 7 by *Heterandria* and area 3 by *Xiphophorus*). By using these assumptions, the *Xiphophorus* cladogram allows the populations in areas 9 and 6 to occur in any of 12 positions and the *Heterandria* cladogram allows area

Figure 14 Consensus tree of the three possible intersecting cladograms of *Heterandria* and *Xiphophorus*. See text for explanation.

Figure 13 Sequence of vicariance events (1–4) for some areas of Gondwanaland hypothesized from the general-area cladogram in **Figure 12**. The area acronyms are as for **Figure 11**. This is just one scenario out of several where an ancestral area gradually divides into four separate areas by successive vicariance events. The taxa are given the same abbreviations as in **Figure 11** and those providing the relational signals are written in bold and roman type.

3 to float onto any of the branches of the cladogram. Thus, of the 425 allowable trees for *Xiphophorus* and the 27 for *Heterandria*, the analysis yields three possible intersections. These are summarized as a consensus tree (Figure 14).

By using this method, we have an area hypothesis that accounts for all 10 areas of endemism (i.e., excluding the hybrid area 11) that can be recognized from the two genera of fishes *Heterandria* and *Xiphophorus*. If the pattern has been created due to changes in Earth history, the question that we could ask now is: "What might have been the historical factors in Mesoamerica to cause this pattern and how might these be compared with the given biological distribution?" Ideally, we would require that geological information be assembled into cladograms, in the same way as biological cladograms, so that biotic and historical patterns can be compared. Until such time as geological data can be ordered for a more informative comparison, one thing we can say is that the observed patterns in species relationships of *Heterandria* and *Xiphophorus* in Mesoamerica have been formed over a period of at least the past 80 million years and are most likely to have been brought about by vicariance events where life and Earth evolved together (Humphries and Parenti, 1999; Rosen, 1978).

Conclusions

At this time, methods of vicariance or cladistic biogeography have proved useful to analyze and compare biotic patterns at the highest resolution and organized in such a way as to compare them to independent sources of data such as geological patterns. Cladistics is a general method of determining class and subclass relations whatever the source of data without recourse to evolutionary narrative. A cladistic approach to Earth history makes it possible to express biogeographic interrelationships as hierarchical relations from biotic information. The development of cladistic methods that cater for the possibilities to consider complicating events but without ever using such information prior to analysis provides a system that allows the possibility of generating general biogeographic hypotheses even from seemingly ambiguous patterns. In other words, vicariance biogeography is a general

empirical procedure without any prior assumptions in the analysis about dispersal, vicariance, redundancy, or extinction events but which at the same time never denies that they occur.

Glossary

Basement complex The layer of highly metamorphosed sedimentary rocks, mainly of late Pre-Cambrian age, that underlies much of tropical Africa.

Catena A regularly recurring sequence of soil and vegetation types developed on an undulating landscape.

Fynbos Habitat type in southern Africa that is characterized by thickets and low shrubs, in which fire plays a dominant role in ecosystem maintenance. Plant endemism is particularly high in these areas.

Inselberg An isolated rock or rocky hill, often of great size (from the German: 'Island Mountain').

Miombo Woodland habitat type widespread in south-central Africa, characterized by numerous species of the tree genus *Brachystegia* and *Isobertinia*, which form nearly closed canopies. Fire is an annual event in this habitat, which supports relatively low populations of large mammals.

Phytochorion (pl. phytochoria) Region within which a substantial proportion of the flora is endemic.

Savanna Tropical seasonal vegetation comprising an upper layer of trees of low stature and a lower layer made up largely of grasses. Fires are a regular feature.

The huge continent of Africa straddles the equator, extending to 37° N and 35° S. It has no marginal oceanic trenches and subduction zones and so lacks the extensive mountain ranges of the Americas, but much of the southern half of the continent is a high plateau close to 1000 meters above sea level, broken only by the southern extension of the Great Rift Valley and the somewhat lower basin of the Congo (Zaire) River. Its great latitudinal range gives it an enormous variety of climates, and this variability is reflected in an extreme diversity of ecosystems. There are three major climatic zones: two at the extreme north and south of the continent, where the main rainfall season is the winter, and one in central Africa, where the rains fall mainly in the hot summer season. The two winter-rainfall areas are distinct from each other and from the tropical parts of Africa. These regions are briefly considered here; a fuller treatment appears in the entry for Mediterranean Ecosystems.

Introduction

White (1983) classified the vegetation of Africa into a number of phytochoria – regions within which a substantial proportion of the plants are endemic. These regions are also useful in helping to define zoogeographical regions, and comparisons can also be made with neighboring continents. Thus the Mediterranean phytochorion of North Africa is most closely related floristically to southern Europe and the Middle East. The Somali–Maasai phytochorion, which occupies the Horn of Africa and regions south to central Tanzania, shows floristic relationships with parts of Arabia and the western part of the Indian subcontinent. On the other hand, about 80% of the plant species that occur in the Guineo–Congolian phytochorion, which occupies the Congo Basin and extends westwards to Liberia, are endemic. The Cape Region, the second winter-rainfall area, is also extremely rich in species, almost all of which occur nowhere else.

The large island of Madagascar, off the southeast coast of Africa, has been isolated from the rest of the continent for over 100 million years and its flora and fauna are very different indeed from those of Africa. The ecology of Madagascar is treated, in brief outline (*see* Madagascar).

Major Environmental Factors of Continental Africa

Geology

Much of southern tropical Africa is a plateau close to 1000 m above sea level, most of which has not been submerged since the Tertiary period. This plateau is formed of Pre-Cambrian ("basement complex") rocks, mainly igneous and much metamorphosed, which have been deeply weathered. The topography of much of the plateau is gently rolling, often with isolated rocky inselbergs, and sometimes with flat-topped hills capped with secondary ironstone, a product of prolonged weathering in high temperatures.

In eastern Africa the plateau has been cut by the two branches of the Great Rift Valley, which extends from Israel to the Zambezi River. Rifting seems to have begun in the Miocene, and was (and still is) accompanied by volcanic activity. In Ethiopia great sheets of basalt were erupted and now form the Ethiopian Highlands. Scattered volcanoes line the branches of the Rift Valley; some, such as Elgon and Kilimanjaro, are now dormant, and others, such as Ol Doinyo Lengai (Tanzania) and Nyiragongo (Zaire), are still active. The Rift Valley contains numerous lakes, some relatively shallow and saline (e.g., Lake Chala (Ethiopia), Lakes Turkana and Bogoria (Kenya), and Lakes Natron and Eyasi (Tanzania)) and others deep and freshwater (Lakes Albert and Edward (Uganda/Zaire), Lake Tanganyika, and Lake Malawi). The blocks between the branches of the Rift Valley have tilted as part of the same tectonic disturbances. This has impeded or even reversed

the flow of rivers, and led to the formation of extensive shallow lakes, such as Lake Victoria, and huge areas of swamp.

Climate

The climate of Africa (excluding the extreme north and south) is determined by the movement of the Inter-Tropical Convergence Zone (ITCZ). As the apparent position of the sun moves north and south with the seasons, the area where the sun is immediately overhead is heated more than the areas to the north and south. The heated air rises, and air is drawn in from north and south to replace it. The convergence of these two air masses, and the rising of the heated air, causes rain. The rain belt tends to lag behind the sun, so the rain belt reaches its farthest north in July–August, rather than at the summer solstice (June 21st), and its farthest south in January–February, not at the winter solstice (December 21st). Away from the equator, the rainfall produced by the ITCZ as it moves in one direction merges into that produced during its return, so that there is a single rainy season. Near the equator, however, there is a tendency for the two passages of the ITCZ to be separated by a dry season, giving two rainy seasons and two dry seasons in each year, but in the wettest regions these gaps hardly occur so that rainfall occurs throughout most of the year.

Superimposed on this basic seasonal pattern is variation in the total annual rainfall. In general, totals decline away from the equator, and also from west to east. In East Africa, air coming from the north-east has passed over the dry Arabian landmass, not the sea as in most of the rest of the continent, and this explains the lower rainfall. Areas close to the sea tend to be wetter than inland areas, except where, as in south-western Africa, cold sea currents offshore produce foggy conditions but low rainfall. Extremes include Sierra Leone, where the coastal capital, Freetown, has over 250 cm of rain each year, most of it falling in four months. Debunsha Point, on the seaward margin of Mt. Cameroon, receives over 10 m of rain in some years; this comes from the combination of a warm sea and rapidly rising ground close to the shore. Rainfall totals increase with altitude up to about 3000 m and then decline. At middle altitudes, the rain is supplemented by moisture condensing from clouds onto leaves and dripping to the ground; here humidity is extremely high for much of each day. Above the cloud layer, however, the climate is drier, and the upper regions of Mt. Kilimanjaro are a virtual desert with probably less than 25 cm of rain each year.

Soils

The soils of much of Africa are developed on ancient land surfaces and are the product of long weathering. Forest soils, developed under high rainfall, are generally very strongly leached, rich in clay, and yellowish brown in color. Drier forests have redder, somewhat less nutrient-poor soils. Savanna soils are often brownish and, again, rich in clay. On the older plateaux there are often regular sequences of soils (“catenas”), with leached sandy or gravelly soils with kaolinite clay minerals on the hill and ridge tops, finer-grained soils on the hill slopes, and deep, dark-colored clays in the valleys.

These valley soils, which shrink and crack as they dry and swell again when they are wetted, become extremely sticky and difficult to work when they are seasonally flooded or waterlogged. These are the so-called “cotton-soils,” rich in montmorillonite clay minerals, in which motor vehicles so easily become bogged.

As a result of prolonged weathering, most of the soils of the African plateau are nutrient-poor, with phosphorus in particular often being in short supply. Some of the more volatile elements, such as nitrogen and sulfur, can be lost in the smoke in the regular dry season fires.

In a few areas, such as the “copperbelt” of southern Zaïre, northern Zambia, and the Great Dyke in Zimbabwe, there are outcrops of soils rich in metals such as copper, cobalt, and chromium. These produce soils that are toxic to many plants. Often trees are scarce or absent, and the vegetation is mainly composed of grasses and a range of specialized herbs, often very local in their distribution.

Fire

The highly seasonal climates of most of tropical Africa provide ideal conditions for vegetation fires. During the wet season, grass growth is rapid, but during the dry season the aerial parts of the grasses dry out and burn very easily. Most of those parts of Africa with a seasonal climate are burned by vegetation fires every year. The exceptions are areas with a rainfall too low to produce the necessary volume of fuel, or so high that the tree cover is continuous and dense, preventing the growth of enough grass to provide fuel. The carbon dioxide produced by this biomass burning is highly significant in the annual atmospheric carbon dioxide budget of the world. Fire has certainly been important in African vegetation for a very long time. Natural fires, at long intervals, can be started by lightning, as well as by volcanic activity. Once humans began to use fire – and some have suggested that this may have been as much as a million years ago – fire frequency would have increased. The acquisition of the ability to make (not just use) fire would have increased this frequency further, and another increase surely came when safety matches became widely available.

The question of the influence of fire on the distribution of vegetation types in Africa has been extensively discussed (Lock, 1998). On the one hand there are the views of workers such as Aubréville, who considered fire to be a major destructive force responsible for the destruction of vast areas of the drier forests of Africa. The converse view, that fire has been a feature of African vegetation for so long that it is now a fundamental part of many ecosystems, is probably more widely held. Though fire may sharpen boundaries between vegetation types, it does not greatly affect their distribution. Assessment of the importance of fire also depends on viewpoint. Foresters generally disapprove of fire and expend much effort in its prevention, whereas pastoralists use fire extensively to remove old grass and to stimulate the development of young grass growth, as well as to check development of woody plants. Foresters, who want trees, generally recommend that fires should be started early in the dry season, when the fuel is still not completely dry (“early burning”). Pastoralists, who want grass, prefer a fire late in the dry season when the fuel is

completely dry and damage to woody growth is maximal ("late burning").

The presence of specific adaptations to fire in a number of plants points to fire having been an important factor for a long time. Several trees, such as the shea-butter tree (*Vitellaria paradoxa*) and species of *Combretum* and *Pterocarpus*, have seeds that, when they germinate, produce what appears to be a radicle that pushes into the ground. However, close examination shows that at least part of this is hollow and is actually formed by fusion of the stalks of the cotyledons (seed-leaves), which remain within the seed. The terminal bud, which lies between the bases of these stalks, is thus carried down below ground level so that it is at least partially protected from fire. Once well buried, the bud starts growth and the shoot breaks out through the side of the apparent root. It elongates and eventually emerges from the ground, but not before producing a number of reduced scale-like leaves, each with a bud in its axil. If the terminal bud is burned away, the lateral buds in the axils of the scale leaves start to develop, giving the seedling another chance of establishment.

Many of the grasses of the fire-swept regions have a long awn on their grains. This awn is hygroscopic, twisting and untwisting with daily changes in humidity. The tip of the grain is sharply pointed and bears stiff hairs. If the point enters a crack, the hairs prevent it from coming out again, and the regular movements of the awn will tend to drive it deeper into the soil, until it is protected from the main heat of the fire.

Past Climatic and Environmental Fluctuations

Tropical Africa has not escaped the climatic fluctuations of the last 2 million years. However, interpretation of changes in Africa is complicated by the effects of rifting and vulcanism, particularly in the east, as well as by the presence of many isolated mountains and mountain ranges. Evidence is also relatively scarce because the peat and other organic deposits that are widespread in cooler regions do not accumulate nearly so readily in tropical lowlands because high temperatures speed decomposition processes. The peat deposits that do exist are mainly on mountains, and so may not present a representative picture of the much more extensive lowlands.

However, there are other kinds of evidence available, such as the extent of active and inactive (fossil) sand dunes. In West Africa the fossil dunes extend 400–600 km south of the present limit of active dunes; the arid period during which these fossil dunes formed appears to have been 12,000 to 20,000 years ago. South of the equator, the Kalahari Sands extend far to the north and east of any presently active dunes, reaching the Zaïre River in the north. It appears that the most recent period of active dune growth coincided with that north of the equator. Lake levels, as marked by raised beaches, can also provide evidence, at least of times when lake levels stood higher than they do now. The study of plant distributions can also sometimes suggest former connections between similar but now isolated vegetation types. For instance, several tree genera with most of their species in West Africa have one or more species in the Eastern Arc montane forests of Tanzania. This suggests a connection between these forests areas in the distant past.

In general, periods marked by cold in high latitudes are correlated with periods of drier and cooler climate in tropical Africa, and warm periods in high latitudes with warmer, wetter, climate. During drier, cooler periods, forested regions contracted and grasslands spread. In the driest times, forests seem to have contracted into a number of refugia, in Sierra Leone and Liberia in West Africa, as well as Cameroon and Gabon, eastern Zaïre, and eastern Tanzania. Most of the evidence shows that there was an arid period between 12,000 and 20,000 years ago (Lind and Morrison, 1974). Prior to this there were certainly similar fluctuations, perhaps of greater magnitude, but their dating and extent are still in dispute. Since 12,000 years ago there have also been changes; the wettest period seems to have been between 8000 and 4000 years ago. At this time, Neolithic pastoralists inhabited large areas of the Sahara and left rock paintings showing elephants, giraffes, and antelopes in areas now far too dry to support them.

Major Phytogeographic and Ecoclimatic Zones of Continental Africa

Mediterranean North Africa

This region, with winter rainfall and hot dry summers, borders the Mediterranean Sea. It includes Morocco, Algeria, Tunisia, Libya, and Egypt. The wettest part is the west, and here also there are the high mountains of the Atlas range. Thousands of years of human settlement, agriculture, and grazing of domestic animals have greatly altered the ecosystems. In Roman times there were certainly lions (*Panthera leo*) (and therefore a substantial prey population) and probably elephants (*Loxodonta africana*) in this region, but all are now gone.

The wetter parts were probably originally covered with forest, but this is now represented only by tiny fragments; *Celtis australis* and *Pistacia atlantica* may have been important trees in the original forests. The drier forests were (and in places still are) dominated by evergreen oak (*Quercus ilex*), which casts a dense shade in which few other species can grow, or by cork oak (*Quercus suber*). There are also coniferous forests of species such as Aleppo pine (*Pinus halepensis*) and North African cedar (*Cedrus atlantica*). Other parts are covered by scrub, similar in physiognomy to the chaparral of California and the fynbos of the Cape Region of South Africa, made up of shrubs with small hard (sclerophyllous) leaves, such as the kermes oak (*Quercus coccifera*), wild olive (*Olea europaea*), and, in very degraded sites, the dwarf palm *Chamaerops humilis*. The shrubs are fire-resistant, sprouting from the base after fires. The gaps between the cushions and, lower down, between the sclerophyllous shrubs support a rich herb flora including many annuals (Fabaceae are abundant and diverse) and many plants springing from underground bulbs or corms (geophytes). These grow during the late winter and spring, flower, and then dry up in the baking heat and drought of the summer. At high altitudes, between 2800 and 3800 m, there is often a low scrub made up of spiny cushions, sometimes graphically referred to as hedgehog heath.

Cape Region of South Africa

The Cape Region also has a Mediterranean climate, although, being in the Southern Hemisphere, it enjoys a hot dry summer when North Africa is having a cool wet winter. Like North Africa, thicket and low scrub (known locally as fynbos) are the main physiognomic vegetation types, and fire is a regular influence on the vegetation. Many species appear to be fire-adapted. Some, such as the red-flowered, lily-like species of *Cyrtanthus*, flower only after fires, stimulated either by chemicals in the smoke or by the greater daily fluctuations in soil temperature that follow removal of the vegetation cover. Others, such as species of *Leucadendron* (a *Protea* relative), retain their seeds on the parent plant and only release them after fire. The range of fire-adapted species in fynbos, and the many ways in which they respond to fires, suggests that fire has been a feature of this vegetation type for a very long time.

The region is extremely diverse geologically and has numerous isolated mountain ranges. These factors, combined with long isolation, have given rise to an extraordinary diversity of plant species – estimates vary from about 7000 species in the 71,000 km² of the region (White, 1983) to 8600 species in an area of 91,000 km² (Cowling and Richardson, 1995, Cowling *et al.*, 1997). The genus *Erica* (heaths) has over 500 species in the Cape Region; other extremely diverse genera include *Aspalathus* (Fabaceae, 250 species) and *Muraltia* (Polygalaceae, 100 species). The family Proteaceae, including 85 species of *Protea*, is prominent among the larger woody plants, and is associated with an endemic pollinator, the Cape Sugar-bird (*Promerops cafer*). The lower-lying and more level areas have largely been converted to agricultural land, but the mountain ranges continue to provide refuges for the endemic flora, although invasion by woody species introduced from other regions with a similar climate (such as south and west Australia) is a major problem.

Originally there was a rich fauna of large mammals but these were heavily hunted by European settlers. Some still survive in reserves, but the quagga (a form of zebra, *Equus quagga*) is extinct, and the bontebok (*Damaliscus dorcas*) and white-tailed gnu (*Connochaetes gnou*) survive only on enclosed farms.

Tropical Africa

The region known as tropical Africa takes in most of the continent. The vegetation is determined by the climate, which is highly seasonal over much of the region. There are virtually no parts of Africa without some kind of a dry period; truly ever-wet climates like that of Singapore (where two weeks without rain is a drought) are virtually absent. The major exception lies along the equator in West-Central Africa; here the dry season lasts a month or less. The equatorial regions of eastern Africa, however, lie within the rain-shadow of the Arabian landmass; here, even on the equator, rainfall is low, and there tend to be two rainy seasons rather than one. Both of these vary in intensity, and the gaps between them also vary in length, so that this region tends to suffer more than most from periodic droughts.

Tropical Africa can be divided into two parts. South and east of a line from Ethiopia to the mouth of the Zaïre River,

most of the land forms a dissected plateau lying at about 1000 m above the sea. This is split from north to south by the Great Rift Valley, which extends from Israel through the Red Sea, then across Ethiopia, Kenya, and into Tanzania. A western branch runs south through Uganda, along the western side of Tanzania, and ends in Malawi. Between the branches of the Rift Valley, the land surface has tilted in places, disrupting river flows and producing the huge but shallow Lake Victoria as well as the extensive swamps of Uganda. To the north and west of the high plateau, the general land surface is much lower. Here again rocks of the Basement Complex underlie most of the region, but younger rocks are found here and there. Most of tropical Africa is covered by woodland and various forms of wooded grassland or grassland, with forest occupying the basin of the Zaire River, and drier bushlands, thickets, and grasslands in the equatorial regions of eastern Africa.

Major Ecosystems of Tropical Africa

Forest

True tropical forest is confined in Africa to two main blocks: the basin of the Zaïre (Congo) River, extending north and west through Cameroon and Gabon into southern Nigeria and eastwards into western Uganda, and a region farther to the west stretching from western Ghana through Ivory Coast and Liberia into Sierra Leone. Elsewhere, isolated forest patches are found inland around the Ethiopian Highlands, along the eastern African coast, and in parts of upland Tanzania (the “Eastern Arc” forests). Recent work has shown that these isolated eastern African forests are rich in endemic plants and smaller animals (Burgess *et al.*, 2004a). Most forests are found where annual rainfall exceeds 120 cm and where the dry season is no more than four months long. Close to the climatic forest boundary, small differences in water availability can greatly affect the vegetation; forest may extend far into grassland along the banks of rivers as “gallery forest,” and nonforest plants can be found well within the forest zone on rocky outcrops.

African forests are poor in species compared to those of Southeast Asia and the Amazon Basin, but they are still species-rich places. Surveys in Ghana found forests in which a 25-by-25-m patch contained more than 200 higher plant species. These surveys also showed that the wettest forests are the most species-rich. They do not, however, contain the tallest trees, which are found in drier, partially deciduous forest, perhaps because the soils there are not so leached of nutrients as those in the wetter areas. These drier forests are, at least in Ghana, richest in the number of timber trees (Hall and Swaine, 1981). The most prominent plant families in the forest canopy are the mahoganies (Meliaceae) and legumes (Fabaceae, particularly the subfamily Caesalpinioidae).

Following disturbance, the pioneers such as umbrella trees (*Musanga*, in Moraceae) and *Trema* (Ulmaceae) grow at 3–4 m per year and rapidly form a tree cover. These species shade the soil and improve conditions for the establishment of trees whose seeds can germinate in shade, and whose seedlings can tolerate low light intensities. These early-successional species include some of the mahoganies, such as *Khaya* and

Entandrophragma (sapele), whose seeds are wind dispersed. Studies in Uganda have suggested that eventually this "mixed forest" may give way to a more species-poor forest in which leguminous trees are common. Some of these leguminous trees form extensive areas of forest in which a single tree species is dominant – an unusual state in tropical forest, for which there is currently no satisfactory explanation. *Cynometra alexandri* in eastern Zaïre and Uganda and *Gilbertiodendron dewevrei* in the Zaïre River Basin form such monospecific forest stands.

Beneath the canopy trees grow smaller trees and shrubs, some of them young plants of canopy species, but others naturally small at maturity. It is usually quite easy to walk through undisturbed forest, as there are few herbs on the forest floor. Only where a tree has fallen, allowing more light to reach the ground, is there a dense mass of quick-growing herbs in the ginger (Zingiberaceae) and arrowroot (Marantaceae) families. Woody climbers (lianas) are also most frequent in disturbed forest, and can reach the tops of the tallest trees.

African forests are rich in animal species. The canopy is occupied by many species of monkey. Some, like the species of colobus (*Procolobus*, *Piliocolobus*, *Colobus*), are leaf-eaters. Others, such as the various small guenons (*Cercopithecus*), feed mainly on fruit (Kingdon, 1997). Different species of guenon specialize on different dietary mixes and several species can thus coexist in the same area of forest. Other tree dwellers include species of flying squirrel, and also true squirrels, most of them seed-eaters.

The great apes – gorilla (*Gorilla gorilla*), chimpanzee (*Pan troglodytes*), and bonobo (*Pan paniscus*) – travel mainly on the ground and feed both there and in the trees. All live in groups and exploit extensive home ranges that they know intimately, moving from one seasonal food resource to another. A high proportion of their food is fruit, and they are important dispersers of seeds. In the wettest and least seasonal forests there are also large ground-dwelling monkeys – the drill (*Mandrillus leucophaeus*) and the mandrill (*Mandrillus sphinx*). Like the apes, they are highly social, living in troops of a hundred or more individuals and traveling over a huge home range.

There are also ungulates in the rain forests of Africa, ranging in size from the tiny royal and dwarf antelopes (*Neotragus pygmaeus* and *N. batesii*, 25–30 cm at the shoulder) and the taxonomically very distinct water chevrotain (*Hyemoschus aquaticus*, only 30–40 cm), through several species of duiker (*Cephalophus*, small antelopes), to the large bongo (*Tragelaphus euryceros*). The Ituri forests of eastern Zaïre harbor the okapi (*Okapia johnstoni*), whose closest relative is the giraffe. All of these are browsers on the leaves of forest shrubs and herbs.

The largest forest animal is the elephant (*Loxodonta africana*). Forest elephants are often recognized as belonging to a separate subspecies from those of open country; they are smaller and tend to have smaller and straighter tusks. Elephants are voracious feeders; their inefficient digestive systems mean that they must feed for a large proportion of each day to obtain enough nourishment. They are particularly fond of clearings in forest, because here more of the foliage is accessible, and by concentrating their feeding in such areas they may prevent tree development and perpetuate the clearings. Elephants also eat large quantities of fruit. Trees such as *Panda*

oleosa, *Desplatsia* spp., and *Balanites wilsoniana* have such large seeds that it is hard to know what animal other than an elephant could possibly disperse them. Attempts to germinate seeds of *Panda* that have not passed through an elephant have been unsuccessful (Hall and Swaine, 1981). The effects on such plants of the widespread decline in elephants may be severe.

Birds are abundant in African forests although the diversity is lower than in, for instance, South American forests. On the ground there are forest species of guineafowl and francolin, as well as the Congo peafowl (*Afropavo congensis*) – the latter confined to the Zaïre Basin. Sunbirds (Nectariniidae) occupy the flower-feeding niche, but also eat small insects. Canopy feeders include numerous species of bulbul and greenbul (Pycnonotidae) as well as small warblers, many in the genus *Apalis*. Some weaver birds (Ploceidae) and waxbills (Estrildidae) are confined to forests, although the majority of both are grassland birds. Parrots, of which the African gray parrot (*Psittacus erithacus*) is the best-known, fly screeching over the forest canopy, seeking fruiting trees. Parrots are, however, very much less diverse than in either South America or Australasia.

Seasonal Tropical Vegetation

Much of tropical Africa is occupied by vegetation that develops under a climate in which the year is divided into dry and wet seasons. The vegetation of these areas is of many kinds, ranging from woodland with an almost closed canopy at one extreme to dry open grasslands at the other. All of these vegetation types have been referred to as savanna, but recently there has been a tendency to attempt to discard this term. It has been argued that a word that can mean almost anything from closed forest to open grassland is too vague to have any utility in ecological discussions. White's (1983) classification avoids the term, and instead uses "woodland," "wooded grassland," "grassland," "bushland and thicket," and "shrubland" to define the various physiognomic vegetation types more precisely. These terms will be used here, but where the term "savanna" has wide currency, as in West Africa, it will be used.

In tropical seasonal vegetation, water is abundant and growth can be rapid during the wet season, but in the dry season the grass rapidly dries out and becomes flammable; fires are frequent and often annual. It is somewhat paradoxical that the fiercest fires occur where the rainfall is highest – and where, therefore, biomass production during the growing season is highest. Over much of the savanna regions of Africa there is one wet season and one dry season each year, but near the equator, particularly in East Africa, there can be two wet and two dry seasons each year (see Major Environmental Factors of Continental Africa: Climate), so that the seasonal cycle is six months rather than twelve.

The herds of wild ungulates and their associated predators for which Africa is so famous are all found in areas of seasonal tropical vegetation. Densities vary enormously, now largely because of human pressures, but there can be no doubt that densities varied greatly before human impacts became significant.

Woodland

In West Africa, where the isohyets (lines of equal rainfall) are more or less parallel to the coast, there are belts of vegetation that follow the isohyets. These woodlands and wooded grasslands were classified many years ago by the great French botanist Auguste Chevalier into three savanna types: Guinea, Sudan, and Sahel. In West Africa, use of the term "savanna" is long established, and Chevalier's zones are still recognized and used today. The southernmost zone, with the highest rainfall and the shortest dry season, is the Guinea Zone (Lawson, 1986).

Woodland has been called by many different names in the African ecological literature. Tree savanna is perhaps the most widely used, as well as the more descriptive "tall grass-low tree savanna." In West Africa, woodland is referred to as "Guinea Savanna," and in francophone countries it is often called "forêt claire." This is a confusing term, because it implies that woodland is essentially the same as true forest ("forêt dense"). This is not the case; surveys in Nigeria of adjacent forest and woodland have shown that they have very few species in common. Physiognomically, woodland consists of a single tree layer, sometimes with an almost closed canopy. Lianas are absent, as are epiphytes. Grass covers the ground beneath the trees.

The trees are often misshapen because the frequent fires kill the growing points and cause branching. Because grass productivity is high, fires are more intense than in other zones. The bark of many of the trees is thick and furrowed, which insulates the delicate growing tissue (cambium) from the heat of fires. Regeneration is difficult as young seedlings are in the hottest part of the fire. Some species, such as the shea-butter tree (*Vitellaria paradoxa*), have specialized germination mechanisms that may help to overcome this. Some grass seeds, mainly those from the subfamily Andropogoneae, also have a mechanism for evading fires (see Major Environmental Factors of Continental Africa: Fire).

The greatest obstacle to the development of the woodlands of Africa (many would say their most valuable conservator) is the tsetse fly (*Glossina morsitans*, *G. pallidipes*, and other species). These biting flies are the vectors of trypanosomiasis, a lethal protozoan disease of cattle, and of sleeping sickness in humans. Wild game animals are immune to trypanosomiasis, although they can carry the protozoan in their blood. Control of the fly has been attempted in many areas, using methods of varying destructiveness to the ecosystem. The fly requires shaded places in which to rest, so tree clearance has been used. Aerial spraying with DDT and other nonspecific insecticides has now been replaced by highly specific treatment with persistent insecticides of the undersides of large tree branches, where the flies rest. Other attempts to break the cycle of transmission have included the removal, by shooting, of wild ungulates. Researchers continue to look for effective and environmentally sound ways of tsetse control. An alternative that has been tried in some areas is to leave the flies alone and harvest the wild game instead of the cattle. This has an advantage in that each member of the diverse ungulate community occupies a different niche, so that the carrying capacity and yield are, at least in theory, higher than those from a monoculture of cattle.

The Guinea Savanna woodlands of West Africa have among their characteristic tree species *Lophira alata* (Ochnaceae) and

Daniellia oliveri (Fabaceae). Slightly drier woodlands have species of *Isobertlinia* (Fabaceae). The main grasses are species of *Andropogon* and *Hyparrhenia*, both with awns on their grains. These large grasses stand 2–3 m high when mature. Many agronomists have been misled into thinking that this high standing crop also implies a high animal production potential, but this is not so. When the grasses are at their tallest, they are made up largely of stem, which is hard, woody, and of very low nutritional value. After a fire, and at the beginning of the rains, nutritious foliage is produced, but this does not last long.

This extreme seasonality in the quality and availability of grass goes a long way towards explaining the relative scarcity of large wild animals in this zone. Various antelopes, such as roan (*Hippotragus equinus*) and eland (*Taurotragus oryx*), occur here, as do smaller species such as bushbuck (*Tragelaphus scriptus*). Elephants occur at least seasonally. Predators are correspondingly also scarce, with leopard (*Panthera pardus*) and lion both occurring at very low densities.

The corresponding zone to the Guinea Savanna south of the equator is the miombo woodland (Frost *et al.*, 2002). "Miombo" is the local name for one of the commonest trees, *Isobertlinia tomentosa* (Fabaceae), but by far the most widespread and abundant trees belong to the genus *Brachystegia* (Fabaceae). There are about 25 species of this genus in the woodland regions of south-central Africa, all fairly similar to one another, mostly variable, and difficult to identify. Miombo covers vast areas of southern Tanzania, Zambia, northern Zimbabwe, southern Zaïre, and south-eastern Angola. Miombo is physiognomically rather different from Guinea Savanna; the trees are usually taller, often with an almost closed canopy, and the grass is somewhat shorter. However, fires are virtually an annual event. Although at first sight miombo woodland can appear rather monotonous, it shows considerable local variations related to topography. The ancient land surface on which it grows is weathered into a pattern of gentle hills and valleys.

The tops of the hills and ridges are dry and well drained, but there are often rock outcrops (inselbergs) around which water accumulates so that the vegetation around them is tall and dense. The rocks themselves, if not sloping too steeply, often bear a shallow turf that dries out completely during the dry season but, during the wet season, becomes saturated and supports many small ephemeral plants such as species of *Utricularia* (bladderworts), *Xyris* (yellow-eyed grasses), and various sedges (Cyperaceae). In West Africa there may be mats of the sedge *Afrotrilepis*, which can dry out completely and then rehydrate and resume growth when water is once again available. In southern Africa there can be clumps of the shrub *Myrothamnus flabellifolius*, the resurrection plant, which behaves in the same way (i.e., it is poikilohydric). These rocky hills are often home to a small and specialized antelope, the klipspringer (*Oreotragus oreotragus*), and to rock hyraxes (*Procavia johnstoni* and *Heterohyrax brucei*).

The typical miombo woodland occurs on the hill slopes, but even this is not uniform. Termite mounds, built by species of *Macrotermes*, can be up to 4 m high and 10 m in diameter. These termites are fungus gardeners; they collect dead plant material and carry it into the center of the nest. Here it is formed into a honeycomb-like structure that is colonized by

fungi that break down the cellulose and lignin in the wood. The termites feed on the fungal hyphae and are thus indirectly nourished by the wood. A by-product of this activity is the concentration of mineral nutrients and fine soil fractions in the mound so that, somewhat surprisingly, it becomes a favorable habitat for plant growth. Termite mounds bear much denser woody vegetation, often casting enough shade to exclude grasses and therefore fires.

The valley bottoms in the miombo ecosystem are seasonally waterlogged, preventing the growth of most trees. Tall grassland occupies this habitat, the grasses often forming well-spaced tussocks between which small plants can grow early in the wet season. The soils of these valley grasslands are often black clays that are extremely sticky when wet and very hard when dry.

A feature of miombo woodland, relevant to concerns about climate change and carbon sequestration, is that the root systems are very extensive so that almost half of the vegetation biomass is below ground. While there is much emphasis on the role of forest destruction on atmospheric carbon dioxide levels, very much less of forest biomass is below ground. The importance of woodlands like miombo to the world's carbon balance should not be underestimated and their value in this respect should be better known.

As in the Guinea Savanna, large mammal biomass is low in miombo. There are, however, many more species than in Guinea Savanna. Roan antelope occur, as well as the closely related sable antelope (*Hippotragus niger*) with its spectacular scimitar-shaped horns. Hartebeest (*Alcelaphus buselaphus*) occur as do elephant where there is permanent water within reasonable range. The spectacular greater kudu (*Tragelaphus strepsiceros*), with long, spirally twisted horns, is very much an animal of the miombo. Herds of Cape buffalo (*Syncerus caffer*) can be found, again where permanent water lies within a reasonable distance.

The annual cycle of the miombo woodland follows the rains. The trees often produce their new leaves before the first rains, presumably drawing on reserves of water from deep in the soil. This flush of new foliage is often reddish, perhaps because of secondary compounds that make the leaves unpalatable to predators. Flowering takes place fairly early in the wet season, giving the often bulky pods and seeds time to develop before the dry season begins. The pods ripen and burst to scatter their seeds during the dry season. The extent to which the leaves are shed varies from place to place and year to year according to the degree of drought and the intensity of the fire.

Drier woodlands are found both to the north and south of the equator. To the north, they fall into the zone called "Sudan Savanna" by Chevalier. This zone has a longer dry season and a lower annual rainfall than the Guinea Savanna. Typical tree species include *Parkia filicoidea* and *Piliostigma thonningii*, but this zone has a much higher human population and is more cultivated than the Guinea Savanna. There are a number of possible explanations for this; maybe all play a part. Because it is farther from the coast, it was less heavily raided and depopulated during the time of the slave trade. The relatively smaller growth of grass makes land clearance and maintenance easier, and the lower rainfall means that the soils are less intensively leached and therefore rather more fertile. Whatever

the reason, this zone now supports high human populations who cultivate groundnuts, sorghum, and various kinds of millet. Many of the remaining trees survive because they are of some use; *Parkia* seeds and the pulp that surrounds them are a useful food, as are the leaves and fruit-pulp of the baobab tree (*Adansonia digitata*).

In southern Africa the corresponding zone is probably mopane woodland, which is not very intensively settled or cultivated. It is dominated by a single tree species, *Colophospermum mopane* (Fabaceae: Caesalpinioideae). Mopane grows in areas that are hotter and drier than those occupied by miombo. It is unusual in its family in being wind pollinated. Mopane woodland can support a wide range of large mammals, including elephant, black rhino (*Diceros bicornis*), eland, and impala (*Aepyceros melampus*).

Bushland and Thicket

The drier lowlands of eastern Africa and the Horn of Africa are occupied by woody vegetation that is low-growing (less than 10 m tall), often spiny, and leafless for a substantial part of the year. The rainfall in this region is always somewhat unpredictable, tending to fall in two wet seasons in each year, either or both of which may fail. The most obvious components of the vegetation are species of *Acacia* (Fabaceae: Mimosoideae). Almost all of these bear paired spines, sometimes hooked and very sharp. Another genus that is abundant and diverse here is *Commiphora* (Burseraceae); all the trees in the genus have a resinous scent and one is the main source of myrrh. (Another genus of the region, *Boswellia* (Burseraceae), yields the resin known as frankincense.)

Many other tree and shrubs occur so that this vegetation type is very rich in species. Few of these are common to the wetter woodland regions, and the Somali-Maasai area is recognized by White as a separate phytochorion; that is, a region with a distinctive flora. The floristic relationships of this area lie with southern Arabia and the north-western part of the Indian peninsula rather than with the rest of Africa. Somalia and northern Kenya in particular are rich in endemic plant species, perhaps partly because of long isolation, but also because of the existence of specialized habitats such as regions where the underlying rock is either limestone or gypsum (calcium sulfate) and the coastal strip near Hobyo (Somalia), where low-growing plants cover fossil sand dunes.

The animals of this area are also distinctive. Grevy's zebra (*Equus grevyi*) and the wild ass (*Equus africanus*) are virtually confined to this part of Africa, and the latter is very scarce. The very handsome and distinct reticulated giraffe (*Giraffa camelopardalis reticulata*) is confined to Somalia, southern Ethiopia, and northern Kenya. The beira (*Dorcatragus megalotis*), a specialized long-legged duiker, is confined to Somalia. The four species of dikdik (*Madoqua*), tiny antelopes that live alone or in pairs in bushland, in territories marked by dung piles, are virtually confined to this vegetation type. Several species of gazelle are also confined, or almost so, to this region. Finally, two remarkable long-necked gazelles, the dibatag (*Ammodorcas clarkei*) and the gerenuk (*Lithocranus walleri*) occur only here; both are exclusively browsers, stretching their long necks up into the bushes and often standing on their hind legs to reach taller growth. Their narrow muzzles allow them to pick out small leaves from between dense twigs or thorns.

The islands of Suqutṛā and Abd al Kūrī to the east of the tip of the Horn of Africa. Both have undoubtedly been isolated for a very long time and have no indigenous large mammals (although introduced livestock now abound). This has allowed the development of a remarkable flora that, although clearly part of the Somalia–Maasai Region, includes numerous endemics such as *Dendrosicyos socotranus* (a tree-forming representative of the cucumber family), *Dorstenia gigas* (Moraceae), and *Adenium socotranum* (Apocynaceae).

Grasslands

Many of the grasslands of tropical Africa are the product of special soils that prevent the growth of trees; seasonal water-logging, shallow soils subject to extreme seasonal droughts, and high concentrations of metals such as copper and cobalt all lead to local grasslands. However, near the equator in eastern Africa there are extensive areas of grassland, sometimes with scattered flat-topped acacia trees (*Acacia tortilis*) or thicket clumps. Most of these areas lie between 1000 and 2000 m above sea level. The commonest and most prominent grass is the red oat grass (*Themeda triandra*). This species thrives under a regime of annual burning and light grazing, but it is vulnerable to overgrazing. Dense tussock-forming grasses such as *Sporobolus pyramidalis* tend to replace it if the grazing pressure is excessive.

These grasslands have long been the territory of pastoral people such as the Maasai, and it is possible that these people, who are well aware of the effects of fire on vegetation, have used it over the millennia to alter the balance from woodland or thicket to grassland on which to pasture their cattle. These people have also long lived in close proximity to huge populations of wild ungulates and their predators. These ungulate populations often make seasonal migrations to make best use of their range, such as that which straddles the Tanzania–Kenya border in the Serengeti and Mara region. The main species in these migratory populations are wildebeest (*Connochaetes taurinus*) and the plains zebra (*Equus quagga boehmii*); other more sedentary species include Thomson's gazelle (*Gazella rufifrons thomsoni*) and Grant's gazelle (*Gazella granti*). In wetter areas, with access to permanent water, other sedentary species such as Cape buffalo, elephant, and waterbuck (*Kobus ellipsiprymnus*) are found. The Serengeti migration is the best-known, but in southern Sudan there is also a huge migratory system involving tiang (*Damaliscus lunatus*), Mongalla gazelle (*Gazella rufifrons albonotata*), and white-eared kob (*Kobus kob leucotis*) (Cobb and Lock, 1988). These species spend the wet season in the tall grasslands towards the Uganda border. When the dry season begins, they move northwards and feed on the swamp grasses, such as *Oryza* (wild rice) and *Echinochloa*, exposed by the retreat of the Nile River floods. This migration crosses the line of the partially dug Jongei Canal – now abandoned due to civil war – which forms a significant obstruction.

The biomass of ungulates supported by some of these grasslands is very high, particularly where there are two rainy seasons each year and therefore at least some forage of good quality at all times. The Western Rift Valley in Uganda and eastern Zaïre is typical; here large herds of elephant, hippopotamuses from the lakes, and Cape buffalo form the main part of the biomass, but other species such as Uganda kob

(*Kobus kob thomasi*), waterbuck, and warthog (*Phacochoerus africanus*) are also common.

In recent years, following the widespread destruction of the larger animals, the smaller ones have increased in numbers. The killing of many of the elephants has also led to widespread vegetation changes. *Acacia* trees, whose seedlings were formerly so regularly browsed and burned that they remained in a suppressed state in the grass, are now regenerating in many places, and thicket clumps dominated by the thorny scrambler *Capparis tomentosa* (Capparidaceae) are now spreading and coalescing to produce larger areas of thicket that are becoming home to giant forest hogs (*Hylochoerus meinertzhageni*), a species more commonly found in montane forests.

In all of these regions with numerous herbivores, there are high populations of predators. Lions are the most conspicuous, living in prides made up of one or more females and their offspring with at least one mature male in attendance. The females collaborate in hunting, and any kill is shared by all the pride. When a new male displaces another, his first action is to kill any cubs in the pride still dependent on their mothers. This action rapidly brings the lionesses into estrus and allows the new male to start passing on his genes with the minimum of delay.

Spotted hyenas (*Crocuta crocuta*) can also be very common and have been shown to function not only as scavengers but also as highly efficient predators in their own right. They live and hunt in matriarchal groups that hold and defend communal territories. The cheetah (*Acinonyx jubatus*) is a highly specialized and solitary cat, entirely dependent on its speed for running down prey. Its jaws are relatively weak, and many of its kills are lost to lions or hyenas against which it has virtually no defense. Finally, there is the wild dog (*Lycaon pictus*). This is another species that lives in groups; hunting is by a prolonged chase in which the members of the pack take turns in the lead. The leaders snap and tear at the hind end of the prey, eventually bringing it down. Wild dogs are short-lived, however, and rely on frequent large litters to maintain their numbers. They usually have a very wide home range and in many areas they are now very scarce or absent, and may well, with the cheetah, be Africa's most endangered carnivores.

The African grasslands are also home to large ground-living birds; some, like the ostrich (*Struthio camelus*), are flightless and others, like the kori bustard (*Ardeotis kori*), almost so. The large mammal populations provide food for scavengers; for instance, a carcass on the Serengeti Plains will attract four or five species of vulture that spend much of their day soaring on thermals; they watch both the ground and each other so that if one spots prey and starts to descend, others quickly follow.

Shrublands

Shrubland occupies the driest areas; under conditions of even lower rainfall the individual shrubs grow farther and farther apart until the land is best referred to as desert. The shrubs are generally between 10 cm and 2 m in height, and are of many different species and families. Members of the Acanthaceae, particularly the genera *Barleria* and *Blepharis*, are often prominent. Many are spiny, and all are highly facultative and irregular in their production of leaves and in their flowering and fruiting, often reproducing only when rainfall is exceptionally high or prolonged. Under these conditions, many annual grasses also appear between the shrubs. Perennial

drought-resistant grasses often occur among the shrubs, and some authorities believe that the natural state in these ecosystems is a drought-resistant grassland, which has been converted to a shrubland by overgrazing. However, at least some shrublands grow on soils developed from limestone or gypsum and so may be partly edaphically controlled.

Deserts

There are two main areas of real desert in Africa: the Sahara to the north of the equator and the much smaller Namib of southwestern Africa. Parts of the Horn of Africa are also extremely dry, but only small areas such as the Danakil Depression can be considered as true deserts, if true desert is defined as an area in which plants grow only where there is extra water either from springs or from runoff.

At least some rain falls over much of the Sahara each year. The exception is the eastern end, in the Nile Valley, where no rain may fall for many years in succession. Over much of the rest, enough rain falls in most years to produce a thin ephemeral vegetation in more favorable areas. Grasses are the main component of this and dry out quickly to form a standing hay that is a valuable food resource for both wild animals and the domestic animals of nomadic herders.

Formerly several ungulate species were not uncommon in the desert: the addax antelope (*Addax nasomaculatus*) and the scimitar-horned oryx (*Oryx dammah*) being the largest, with several smaller species of gazelle. Most of these have extremely efficient water-conserving strategies and are capable of surviving without drinking. Human population increase, with concomitant competition for space, grazing, and water, and the increased availability of firearms, mean that all of these species are now rare and endangered, and the scimitar-horned oryx is now officially extinct in the wild. Scattered over the desert are oases where springs from underground aquifers provide year-round water. Most of these oases support permanent human settlements, often dependent on sparse annual crops as well as dates produced by the date palms (*Phoenix dactylifera*) that thrive in these environments.

The Namib Desert in southwestern Africa is also very dry, at least near the coast, but the dryness is mitigated by frequent fogs arising from the cold Benguela Current immediately offshore. Many of the plants and animals in this region survive by collecting water from mist. Furthermore, a few rivers cross the coastal strip, forming linear oases in which water is almost always available. Animals such as gemsbok (*Oryx gazella*), and even a few herds of elephants, manage to survive in this harsh environment.

One plant family, Mesembryanthaceae, has speciated enormously in this region, and there are hundreds of species. Some of these are very simple in structure, producing clumps of short shoots each bearing just one pair of large thick leaves at any one time. The lower parts of these leaves are buried in the soil, thus avoiding the extreme heat of the surface, and the exposed surface is often translucent, allowing light to reach the buried part of the leaves. The exposed parts of the leaves are also often colored and textured just like the surrounding stones, which camouflages the plants; the members of one genus, *Lithops*, are known as "living stones." One truly remarkable plant grows in this area and nowhere else in the World – *Welwitschia mirabilis*. This is not a flowering plant, and

neither is it a true conifer. Each plant consists of a thick woody stem, mostly buried in the ground, bearing two huge strap-shaped leaves that grow continuously from the base, lie on the ground, and wear away at the tips.

Montane and Afroalpine Ecosystems

Mountains in Africa are of two kinds: relatively recent volcanics such as Mts. Cameroon, Kilimanjaro, Elgon, and Kenya and the Ethiopian Highlands, and old up-thrust portions of basement complex such as the Ruwenzori Mountains and numerous lower ranges in Tanzania such as the Usambara, Uluguru, and Udzungwa Mountains.

Mountain slopes were originally forested, but because of their fertile soils the forests have been cleared for cultivation in many places. However, the higher forests tend to be cool and misty and much less attractive for agriculture, and some of these survive. Trees such as podocarps (*Podocarpus*, *Afropodocarpus*) and the mountain bamboo *Synarundinaria alpina* are common. Epiphytic bryophytes, ferns, and orchids are abundant. Above the montane forest is a belt of "giant heath" formed from large species of *Erica* that attain 10 m in height. As in the montane forest, epiphytic mosses and liverworts are very abundant, often forming dense mats covering the trunks and branches of the giant heaths.

Above the heath zone lies the afroalpine zone proper. The climate here has been described as "summer every day and winter every night." Hot sunny days (this region is often above the cloud zone) are followed by nights during which the temperature plunges to well below freezing, and frost and ice forms on the ground. Here giant groundsels (*Dendrosenecio*) and giant *Lobelia* grow scattered in a low shrubland of everlastings (*Helichrysum*) and *Alchemilla*. The giant groundsels and giant lobelias consist of rosettes of huge leaves borne at the ends of sparsely branched stems. (A very similar growth form is found in the genus *Espeletia* of the Andean paramos.) During the night, the leaves fold upwards to form a dense mass around the delicate terminal buds, thus protecting them from the cold. Water and mucilage accumulate in the rosette and also help to prevent the buds from freezing. The old leaves of some species do not fall, but accumulate as an insulating blanket around the stems; other species have thick corky bark that functions in a similar way.

Animals are generally sparse in montane forests and in the afroalpine zone. Various antelopes move up here from the surrounding savannas, as do elephants and the occasional buffalo. With these come predators, particularly leopards. Specifically montane animals include the mountain nyala (*Tragelaphus buxtoni*) of the heath zone in Ethiopia, and the giant forest hog, a huge, hairy, black pig that occurs in the montane forests of Kenya and elsewhere, but also at lower altitudes in western Uganda. Montane forests are rich in bird species, some of them occurring nowhere else. The giant lobelias are visited and pollinated by sunbirds, which are specialists on them.

Wetlands

The wetlands of Africa may be seasonal or permanent. Warping and subsidence of the earth's crust has produced several

extensive wetland areas, such as the inland delta of the Niger River in Mali, the Sudd of the Nile River in the Sudan, the inland delta of the Okavango in Botswana, and the Bangweolo swamps of northern Zambia. Many permanent swamps are dominated by the giant sedge *Cyperus papyrus*. Papyrus requires at least some water movement and a reasonable supply of nutrients to thrive; when it does, it attains heights of 3 m or more. Papyrus swamps are very species poor. There are few other plants, most of them climbers like the purple morning-glory, *Ipomoea rubens*, and the yellow-flowered pea, *Vigna luteola*. A swamp antelope, the sitatunga (*Tragelaphus spekei*), shelters in papyrus but finds little food there. Some birds, such as the golden-crowned gonolek (*Laniarius mufumbiri*) (a shrike) and Carruthers' cisticola (*Cisticola carruthersi*) (a small brown warbler) spend their whole lives in papyrus swamps, but most of the herons and other waterbirds are found along channels and at the swamp margins. A most striking bird of African wetlands is the shoebill (*Balaeniceps rex*), a large-billed stork that lives in the depths of swamps and feeds on fish.

Temporary pools are a common feature of the seasonal region of Africa. A pool will fill early in the rainy season, sometimes from rain and sometimes from overspill from rivers. Fish usually reach all but the most isolated pools; the air-breathing African lungfish (*Protopterus aethiopicus*) can survive in a mucous cocoon in the mud for many months, emerging when water returns. Catfish (*Clarias*) can move over land through wet grass, and species of killifish survive as resistant eggs in the mud, hatching when wetted.

Floating plants like the Nile cabbage (*Pistia*) and water lilies (*Nymphaea*), as well as submerged plants such as bladderworts (*Utricularia*) and hornwort (*Ceratophyllum*), appear from seed in the mud. In game reserves and parks hippopotamuses (*Hippopotamus amphibius*) often move into the pools and churn them into mud, as well as adding nutrients in their droppings. At the end of the wet season the pools start to dry up. Then flocks of herons, egrets, and storks arrive to feed on the fish trapped in the shrinking patches of water, and the hippos move back to permanent water or die.

Seasonally flooded grasslands are found around the edges of many of the swamp regions of Africa. Some of them, like those around the Sudd of southern Sudan, and the Kafue River flats of Zambia, are very large. Among the grasses, species of *Echinochloa* are often common; at least some of these are very tolerant of flooding and their stems can elongate and form a floating mat when water levels are high. Perennial wild rice (*Oryza longistaminata*) is also common. Many of these areas are occupied by pastoral groups such as the Dinka of southern Sudan. They are cattle herders and move seasonally to follow the rise and fall of the flood. There are also wild ungulates; the Nile lechwe (*Kobus megaceros*) is confined to the grasslands at the edges of the Sudd swamps, and the red lechwe (*Kobus lechwe*) is found in various seasonally flooded grassland areas of Zambia. These animals also follow the rise and fall of the flood.

Lakes

Africa has numerous freshwater lakes, some of them very large. They are either shallow or deep lakes. First, there are the deep lakes of the Rift Valleys: Lakes Tanganyika (33,000 km²,

maximum depth of 1460 m), Malawi (704 m), Edward, and Albert. These lakes are permanently stratified. In the temperate zones, low winter temperatures cool the surface waters to 4° C, at which temperature water is densest and sinks, carrying dissolved oxygen to the bottom of the lake. In the tropics there are no significant seasonal variations in temperature, the surface water is always warmer than the depths, and there is little circulation, so that the deeper layers are anaerobic and lifeless. In spite of this, the oxygenated upper layers have a rich fauna and are highly productive. These lakes are ancient, and speciation within them has been rapid. The diversity of molluscs in Lake Tanganyika, for instance, parallels that of the sea, with thick-shelled species occurring on exposed coastal rocks and species with long spines on the shells living on soft mud bottoms. The fish faunas also parallel those of the sea, with some species living among rocks near the shore, while others exploit the zooplankton and other food in the open water.

Then there are the shallower lakes, such as Lakes Victoria (69,000 km², maximum depth of 90 m), Kyoga, Chad, and Bangweolu. In these lakes the stirring action of the wind is enough to circulate the water and carry oxygen to the lake bottom. Most of the shallower lakes are relatively young in geological terms, but some of the groups of fishes in them have speciated explosively to produce "species flocks," each of whose members exploits a different, often extremely specialized, niche.

In Lake Victoria, which is less than a million years old, the cichlid mouth-brooding genus *Haplochromis* is represented by more than 150 species, including plant-eaters, snail-eaters, and fish predators. More bizarrely, there are also species that live by biting off scales and portions of the fins of others, by pulling mayfly larvae from their burrows in dead wood, and by (probably) sucking the eggs and young from the mouths of brooding females of other species. Sadly this astounding diversity is under extreme threat following the introduction of the Nile perch (*Lates niloticus*) to the lake. This is a voracious predator, formerly found only in the Nile system below the barrier of the Murchison Falls, but now introduced to Lake Victoria with the intention of increasing fishing yields. Water hyacinth (*Eichhornia crassipes*) has also been introduced to Lake Victoria and is altering the ecosystem enormously by forming extensive mats at the edge of the lake, which make access for fishing difficult. (These mats may also, however, be providing nursery areas for young fish.) Both Lake Malawi and Lake Tanganyika (deep lakes) have a similarly remarkable diversity of cichlid fishes and, so far, neither Nile perch nor water hyacinth has been introduced to them.

Finally, within the Rift Valley there are a number of lakes that are highly alkaline or saline. Soda (sodium carbonate) is obtained commercially from Lake Magadi in Kenya, and salt (sodium chloride) from Lake Katwe in western Uganda. The soda lakes of the western Rift Valley in Ethiopia, Kenya, and Tanzania, as is often the case with extreme environments, support relatively simple ecosystems in which a few species are present in great abundance. A planktonic blue-green alga, *Spirulina*, often forms almost a soup in the alkaline water. Planktonic copepods (small crustaceans) and chironomid (midge) larvae feed on the algae. Lesser flamingos (*Phoenicocnais minor*) also feed on the algae by filtering water through their beaks. Greater flamingos (*Phoenicopterus ruber*) have more widely spaced filters in their beaks, and feed mainly on

the larger copepods and midge larvae, often stirring them out of the mud with their feet. They are not as numerous as the lesser flamingos. Both species migrate up and down the Rift Valley in response to changes in water levels and algal concentration. They breed in huge colonies when water levels are right and food availability is maximal.

Coastal Ecosystems

Most of Africa's seashores are sandy or muddy; rock is rare and generally confined to isolated headlands. Coral reefs occur along the east coast from the Red Sea to Mozambique, but not in the west, where cold upwelling water and turbidity virtually exclude them.

The strand lines of sandy shores support open communities of creeping plants such as *Ipomoea pes-caprae* (Convolvulaceae), *Canavalia rosea* (Fabaceae) and *Remirea maritima* (Cyperaceae). The first two have large seeds that float in seawater and are probably thus dispersed; both species occur widely in the Old World tropics. On the landward side of this grow salt-resistant bushes of species such as *Sophora inhambanensis* and *Pemphis maritima*, often forming dense thickets. Such thickets may grade into forest, or, in parts of West Africa, into a wind-swept grassland with bush clumps sculpted by the wind. Some of the grassland plants exist here as prostrate ecotypes that maintain their prostrate growth form in cultivation.

More sheltered shores often support mangrove swamps, particularly in the neighborhood of the mouths of large rivers such as the Niger and the Rovuma (Tanzania). West African mangrove swamps are relatively poor in species; *Avicennia* and species of *Rhizophora* are frequent here. The east coast is richer in species. The mangrove ecosystem is extremely productive; the breathing roots of the mangroves support communities of seaweeds and oysters, while the mud surface teems with crabs and small fishes. The whole zone is a rich nursery for fish.

Some of the more sheltered sandy flats behind reefs, particularly in northern Kenya and southern Somalia, have extensive beds of seagrasses (*Cymodocea*, *Halodule*, and *Thalassodendron*) (Richmond, 1997). These are not true grasses, although their flat, parallel-sided leaves are similar, but are closer to the pondweeds (Potamogetonaceae). Some grow intertidally, but many extend well below low-tide level and may form extensive lawns on sandy substrates. Here they are grazed by dugongs (*Dugong dugon*). These marine vegetarian mammals are regularly hunted and are becoming scarce and endangered almost throughout their range.

Madagascar

Madagascar has been isolated from Africa for at least 140 million years, and from India for around 88 million years. It has a rich flora in which about 84% of the species are endemic, and in at least some cases their closest relatives occur in southern Asia rather than Africa. There are five endemic plant families and 321 endemic genera. The isolation of Madagascar predated the major adaptive radiation of mammals that has occurred in Africa, and it lacks large grazing mammals – although a dwarf hippopotamus appears to have become extinct less than 1000 years ago – and large carnivores.

At present the largest wild mammal is the bush pig (*Potamochoerus larvatus*), which is believed to be a recent arrival. A group of primitive primates, the lemurs, has radiated into all the habitats on the island. Fossils show that they were formerly even more diverse than they are now; some extinct forms were much larger than any modern species. The largest carnivore is the fossa (*Cryptoprocta ferox*), a large mongoose-like animal that climbs trees well and is a specialist predator on lemurs. There are also fossil and subfossil remains of giant flightless birds (*Aepyornis*), the last of which seem to have become extinct only a few hundred years ago. Humans reached the island from the east perhaps 1500 years ago. At first their settlements were confined to the coast, but later they spread inland and colonized the central plateau. Humans have had a dramatic effect on the island's natural vegetation and habitats.

Flowering plants were in their earliest stages of evolution when the island became isolated, and a high percentage of species (80% in the legumes, Fabaceae), many genera, and some families are endemic. The vegetation of the island is very varied. On the eastern side, rainfall is high and there is little or no dry season. Here there are tropical rain forests, very diverse in composition, with no single species being dominant. They differ from the forests of mainland Africa in their lower stature (25–30 m), lack of large emergent trees, the abundance of small palms in the understory, and the frequent occurrence of climbing bamboos. These forests have been considerably reduced by clearance for agriculture, and only scattered fragments remain. Secondary forests are widespread, often characterized by the distinctive traveler's tree (*Ravenala madagascariensis*), with a single stem crowned by huge leaves arranged like a fan in two opposite rows. Higher up the forest takes on a more montane aspect; the trees are shorter and more branched, and epiphytic ferns and mosses are abundant. The highest mountains support a montane thicket of small-leaved ericoid shrubs such as *Erica* (Ericaceae), *Stoebe* (Asteraceae), and everlastings (*Helichrysum*, Asteraceae) (Koechlin *et al.*, 1974).

A drier form of forest or woodland seems also to have occupied much of the central plateau, but only tiny fragments remain, and these are under intense pressure from fire, agriculture, and wood cutting for charcoal. The commonest tree is tapia (*Uapaca bojeri*), which may owe its survival to its fire resistance. One legume genus with two species, *Peltiera*, has recently been described from forest fragments in this zone; only three specimens and no living plants are known and it seems likely that the genus was extinct before it was described. The forests of the central plateau have largely been replaced by a species-poor grassland that provides little protection to the soil from erosion so that gullies are widespread and deep.

In the western half of the island, dry deciduous or semi-deciduous forest survives here and there, particularly in limestone areas, which have often weathered to produce an inhospitable landscape of sharp ridges and pinnacles ("tsingy") that is very difficult to access and unsuited to any kind of agriculture.

The southern end of the island, particularly in the west, is very dry, and here a peculiar thorn forest is found in which the endemic cactus-like family Didieriaceae is common. Specialized lemurs (sifakas - *Propithecus verreauxi*) live in this thorn forest. This remarkable vegetation type is threatened by agriculture, particularly sisal cultivation, by grazing, and by cutting

for charcoal production. Perhaps because of the absence of large grazing animals, members of several plant families have developed a growth form in which leaves are absent and photosynthesis is carried out in the flattened stems. Several members of the family Fabaceae show this feature.

Another plant growth form perhaps more widely developed in the dry parts of Madagascar than in any other region is the "bottle-tree," in which a thick and swollen trunk supports a rather small crown. The genus *Adansonia*, with one species in Africa (the baobab) and one or two in Australia, has seven species in Madagascar. The flame-tree (*Delonix regia*), now an extremely widespread ornamental tree in the tropics, is one of ten *Delonix* species in Madagascar, with just one other in tropical Africa. Several of the Madagascar species are bottle-trees.

Some of the richest habitats in Madagascar are the rocky outcrops, perhaps because they are sheltered from fires and grazing animals. Numerous endemic species of *Aloe* and succulent spurges (*Euphorbia*), as well as strange single-stemmed spiny succulents (*Pachypodium*), are common on these rocky outcrops and make them striking refuges for the remarkable flora of this isolated island.

The Future for African Ecosystems

What of the future? The human species has been present in Africa for longer than in any other continent. For much of the time, however, humans would have lived as part of the normal ecosystem – essentially part of the wild fauna. Exactly when they began to rise to dominance and to influence the composition and distribution of ecosystems is hard to say. There is some evidence that humans have been using fire (although probably not making it) in Africa for as long as a million years. Fire is one of the most potent forces for change in tropical vegetation and an increase in fire frequency caused by humans may well have shifted the balance between woody and herbaceous vegetation towards the latter. The southward spread of pastoral peoples, with their knowledge of the power of fire to produce new grass and control trees, seems to have begun by at least 2000 years BC, perhaps in response to increasing Saharan aridity, and may have been an important force for vegetation change.

Domestication of crops may well have begun at the same time. African plants that have been domesticated include yams (*Dioscorea*), sorghum, upland rice (*Oryza*), and cowpea (*Vigna*), with oil palm (*Elaeis*) in the forest zone. Bananas (*Musa*) probably arrived from Asia in the first millennium AD, and New World crops such as maize (*Zea*), cassava (*Manihot*), tomato (*Lycopersicum*), and peppers (*Capsicum*) did not arrive until the fifteenth or sixteenth centuries AD.

Most of the people of Africa survive by subsistence agriculture, or by growing crops that are sold to the rapidly increasing town populations. Shifting cultivation, in which a piece of ground is cleared, cultivated for a few years, and then abandoned for a fallow period of varying length, is the traditional way of exploiting the nutrient-poor soils characteristic of much of Africa. Although this practice is often attacked as wasteful and destructive, it is a very satisfactory mode of land use, so long as population densities remain low and a long fallow period is possible. However, once populations increase, the length of the fallow period falls, as do yields. This increases

pressure to find new agricultural land, such as may be opened up in forest by logging activities. The extraction roads that allow people into the forest and the clearings made during timber cutting provide sites for settlement. It is often said that most of the forest loss in Africa is not caused by timber extraction, but rather by the subsequent settlement.

Large-scale intensive agriculture, such as has led to the destruction of huge areas of tropical woodland in South America, has barely touched Africa. There are, however, signs that some countries outside Africa are looking to its relatively lightly populated regions as a potential 'bread basket' to address their own problems of food security. Large-scale commercial agriculture would not only impose heavy loads on fragile ecosystems, but also displace traditional farmers whose practices are in tune with their environment.

Human populations are increasing throughout Africa, in some nations at alarming rates. It is easy to overlook that an annual increase of 3.5% implies a population doubling every 15 years, and such rates are found in several African countries. Probably a majority of Africans are aware of the problem, but the absence of state care for the old is a considerable incentive to produce numerous children; even if child mortality is high, at least some will survive to provide care for the parents in their old age. Improvements in health care tend to come before reductions in birth rates, leading to lower death rates and longer life expectancies.

A rise in population increases the pressure on land, and therefore on natural ecosystems. Cultivators spread farther into areas moist enough for agriculture, and irrigation schemes push out the cultivable boundaries. Pastoralists increase their flocks and herds, which are viewed as cash on the hoof, whose numbers tend to increase until drought or disease cuts them back. Some of the more natural ecosystems, such as those of seasonally dry regions with high wild animal populations, are enclosed in national parks or game reserves, but unless these are very large they are invariably inadequate to accommodate migratory species or those, like the elephant, that normally range over a very wide area. Within the parks and reserves, tourist pressure can also be a problem.

Political instability and the wider availability of firearms are other threats. All of the larger antelopes of the Sahara and its fringes are now endangered because of hunting with guns and motor vehicles, as well as competition with domestic stock for forage and water. The migratory animal populations of southern Sudan have been greatly reduced by hunting with the many firearms now in the region. The state of the endemic large mammals in war-torn Somalia is largely unknown. In the 1970s and 1980s, elephants were hunted throughout Africa for their ivory.

Undisturbed forest is now a rare commodity in the whole of West and East Africa; only in the Congo River Basin are there tracts still in their original state, protected by their size and inaccessibility (Burgess *et al.*, 2004b). Exploitation of forests for timber will no doubt continue and probably intensify, not only for timber for export and internal use but also for charcoal to fuel the cookers of the cities. Additionally, more areas will be cleared for plantation agriculture and for cash crops such as oil palm and cocoa. The woodlands will continue to be heavily exploited for firewood and charcoal, and more favorable sites will be cleared and converted to large-scale agriculture, if soil

fertility can be maintained. Fire frequency in the grasslands will continue to increase as the human population increases, although the spread of agriculture tends to reduce fire by fragmenting the area that can be burned.

Yet here and there are signs that change may be taking place. In West Africa there is a tradition of preserving a patch of forest near every village to provide a burial ground, a home for the ancestral spirits, and a source of plants for medicine and poles for building. These sacred groves provide refugia for some forest species. In parts of the Guinea Savanna zone, schemes for sustainable exploitation of the woodlands for firewood and charcoal have been developed and may be taking hold. Overall, however, the future for many plants and animals in Africa, particularly those of the forests, is still bleak.

Glossary

Alpine Refers to the life zone above the climatic high-elevation treeline, irrespective of latitude. Though originating in the Alps (a pre-Roman word for high mountains), the term is applied globally. The reader should be aware that this term is often used in a much wider sense in common language, and is also applied to regions with mountains in general, including settlements and resorts, which is not the scientific meaning here.

Apomixis A very common but “hidden” mode of clonal propagation by seeds, the embryos of which are 100% genetic copies of the source plant. Seeds are produced without fertilization, but often pollination is required to induce apomictic seed production. Apomictic plants also reproduce sexually, but these are very rare events.

Clonal growth A vegetative mode of propagation and expansion of plants by runners, tillers, or plant fragment dispersal, which is very important in the alpine life zone. (See also apomixis.) Clonal plants also produce sexual offspring by seed, but their clonal propagules often show higher survival. All clonal offspring of one source plant have the same genome and hence belong to the same “genet.”

Ecotype or ectotypic Refers to genetic (evolutionary) differentiation within a given species (a specific “race”) that reflects an obvious advantage in a given environment. Ecotypic traits are retained when individuals are

transplanted into a different environment where these traits have no advantage.

Life-form The size and stature of a plant under natural life conditions. Environmental constraints can cause the life-form to differ substantially from that of a plant that develops under more favorable conditions, where genotype morphology, the “growth form,” finds full expression. For instance, the growth form “tree” may be modified to the life-form “shrub” in the alpine zone.

Microclimate The climate that plants, small animals, and soil microbes experience, and that differs substantially from the “macroclimate” reported by weather stations. This difference is related to surface warming by the sun or cooling at night, as well as wind shelter effects, and is largely driven by relief, exposure, ground cover, and plant stature.

Treeline Also known as the forest line, this describes the high-elevation limit of (usually fragmented) forest. Most often there is no “line” visible in the landscape, so treeline position represents a convention. “Outpost” tree individuals may occur at higher elevations (the tree species line), and the boundary of closed, tall forest with timber-size stems (the timber-line) commonly occurs at an elevation that is 50–150 m lower. The whole transition from timber-line to the tree species line is called the “treeline-ecotone.”

The Alpine Life Zone

The lower boundary of the alpine life zone is, by definition, the natural climatic high-elevation treeline. Where a treeline is missing, as is the case in some dry continental areas or because of deforestation, the treeline-isotherm is still applied, irrespective of the presence or absence of trees. This is nothing more than a practical convention. The actual natural treeline and hence the lower end of the alpine zone do not form a sharp boundary, for patches of stunted trees and alpine plants often intermingle. This transition zone is termed the ‘treeline-ecotone’. The common climatological denominator of this boundary is a mean temperature during the growing season of 6.5 °C, with a minimum length of the growing season of 94 days (Körner, 2012); this definition applies worldwide (see the discussion in Körner, 2003). The length of the growing season within the alpine life zone varies from 12 months in the tropical alpine zone to merely 4–6 weeks in alpine snowbed vegetation at higher latitudes.

About 4 million km² fall into the alpine life zone (ca. 2.6% of the global land area outside Antarctica). Because not all of this alpine area is covered by vegetation – some consists of bare rock, rock fields, scree, and glaciers – the vegetated alpine

land area is estimated to be ca. 3 million km² (see Körner *et al.*, 2011).

Two-thirds of the global alpine area is situated in the temperate and subtropical zones and only 10% occurs in the tropics (Table 1). Partly this is because mountains in the tropics need to be very high, at least 3600–4000 m, to permit tropical alpine vegetation to occur, whereas at the polar circles mountain heights of only 600–800 m are required to support alpine habitat. These are the approximate treeline elevations of the respective climatic zones. At about 4000 m, treeline reaches its average highest elevations in the subtropics (local extremes up to 4900 m, Figure 1). At high latitudes (> 65 to 70° N), alpine vegetation merges with arctic tundra. Despite a number of common taxa and the overwhelming influence of low mean temperature, the arctic tundra life zone is very different from the alpine zone in terms of climate, land surface structure, and vegetation, hence several authors (e.g., Löve and Billings) have recommended that alpine vegetation not be referred to as “alpine tundra.” The upper limits of vascular plant occurrence are commonly 1000 to 1500 m above the lower limits of the alpine zone (the treeline), but some extreme high-elevation outposts of higher plants are found up to 4500 m in the temperate zone and up to 6400 m in the

subtropics, where the uppermost individual of a higher plant was found in the Himalayas (Miehe, 1997). An important feature of alpine life is its isolation. Mountaintops with their high biological diversity represent islands or archipelagos surrounded by lowlands, where most alpine organisms cannot survive (Table 2).

Various aspects of plant diversity in high mountain systems have been reviewed previously. A selection of such synthetic papers or volumes is included in the References. Full bibliographic references to original studies (mentioned in the text by authors' names only) can be found in Körner (2003).

Habitat Diversity, a Key to Alpine Plant Diversity

Climatic Microhabitats

There is a common belief that the alpine life zone is very hostile to plants and animals and that low temperatures restrict life activities, including productivity. This generalization is wrong for two reasons: (1) as will be shown, temperatures are not always that low, and (2) this belief reflects our human perspective of what is "cold." For organisms adapted to alpine life conditions the temperatures they experience are not

necessarily “cold.” In fact, if temperatures were higher, most of these organisms would suffer or even die, many of them because they would be outcompeted by other species that do better at such higher temperatures.

The most important characteristic of the alpine life zone is its fragmentation into a multitude of microhabitats created by relief, exposure, and slope, which interact with solar radiation and wind to cause soil moisture, temperature, and substrate quality to vary enormously over very short distances (Scherer and Körner, 2010). It is this diversity of microhabitats, the steepness of the terrain in particular, that makes the alpine life zone so different from arctic tundra, and that is responsible for its much greater organismic richness. Across a few meters one can easily find snowbed plants, just emerging from melting snow, and succulent plants on outcrops, which perform crassulacean acid metabolism (CAM) as do many hot desert plants. In fact, these succulents may regularly experience temperatures close to 50 °C on steep south slopes under full midday sun, even at high latitudes.

In addition to these microclimatic determinants imposed by land surface structure, plants themselves influence their micro-environment (Figure 2). Depending on life-form, plants may decouple themselves from ambient air conditions. Under direct insolation, compact cushion plants or prostrate dwarf shrubs have been shown to warm up to tropical temperatures. These life-form-dependent microclimates largely disappear under thick clouds or at night, but storage of warmth in the topsoil is also strongly influenced by the type of plant cover, and so is radiative cooling during clear nights.

Hence, the climate that alpine plants experience can be very different from what might be expected based on elevation alone or data measured at weather stations. Such weather data monitor the temperature, humidity, and windspeed that occur outside the calm boundary layer into which alpine plants (leaves in particular) and their animal and microbe partners are commonly nested. A widespread assumption is that alpine plants are small and prostrate because their growth is

temperature limited. The reality is that, because alpine plants are small (and mostly stay small when grown at higher temperatures), they may periodically escape the cold and, at least during sunny hours, experience radiative warming, and thus are not always colder than lowland plants. This is well reflected in their thermal optima for photosynthesis, which (in the temperate zone) were shown to be similar to those of lowland plants. In contrast, night-time temperatures may be prohibitive for plant growth at alpine elevations, and thus limit structural investments of assimilates acquired during the day. Because of the strong link between plant life-form and microclimate, alpine biodiversity can be understood only if one accounts for plant structural diversity.

Diversity of Substrates

Alpine microhabitats may belong to a suite of different land surface structures and soils, the ten most important of which are common to all mountains:

- exposed rock terraces and rock crevices
- block fields scree and mixed scree/rock slopes or flats
- drained ridges and plateaus
- periodically wet depressions, gullies, or snowbeds
- gentle slopes with relatively stable soil
- steep slopes with creeping soil
- flats with cryogenic structure (e.g., hummocks, polygons)
- mires or other wet ground
- springs, water flows, or lakes.

These ten habitat types are not exhaustive. Special habitats not found everywhere include sand drifts or dunes and salt flats (in some semiarid subtropical mountains), disturbed surfaces due to animal trampling, rest places, or burrowing, avalanche tracks, and man-made landscapes such as pastures.

Each of these types of habitats may be found at different exposures to sun and wind (so the number of substrate types multiplies with the number of microclimatic conditions, despite some redundancy), and each of these combinations in turn may be found on very different parent rock material such as calcareous or siliceous, mixed metamorphic, or volcanic material. Depending on wetness and elevation, plants may have converted the top layers of the substrate to an extent that it becomes chemically independent from the parent rock (e.g., humic turf of pH 3.7 overlaying calcareous bedrock). Varying degrees of erosion and soil formation will then enhance the spatial heterogeneity of the substrate. The availability of soil nutrients and the extent of soil development are strongly relief driven, but plant life-forms also determine local nutrient retention. By forming dense cushions or tough tussocks, plant litter and thus the precious nutrients contained in it are prevented from being blown or washed away. When trapped beneath or strongly attached to the plant, litter can decompose and nutrients can recycle locally. Plant life-form, root and rhizome structure in particular, also influences substrate stability and soil formation (see Potential Functions of Alpine Biodiversity).

To understand alpine biodiversity, it is important to be aware of this extensive microenvironmental patchiness of the alpine life zone, and the capacity of plants to influence their

Figure 2 The diversity of plant morphologies creates diverse microclimates. Note the different temperatures in upright and prostrate leaves of two species in the Ecuadorian Andes. Reproduced from Diemer MD, in Körner Ch (2003) *Alpine Plant Life*. Heidelberg, Germany: Springer.

life conditions substantially. Taken together, the foregoing combinations of microenvironmental conditions yield hundreds of very specific niches, each preferred by a different combination of species.

Plant Diversity in the Alpine Life Zone

Diversity of Morpho-types

Though the alpine life zone is not as rich in life-forms as a humid tropical forest, the diversity of morpho-types found here is surprisingly high. There are ten principal groups of life-forms, eight of higher plants and two of cryptogams, irrespective of whether individuals perform clonal growth. The first four groups are most important:

- low stature or prostrate woody shrubs
- graminoids such as grasses and sedges, many forming tussocks
- herbaceous perennials, often forming rosettes, and
- cushion plants of various types.

Less common or of more regional importance are:

- giant rosettes of tropical mountains
- geophytes, mainly confined to mountains with a pronounced seasonality
- succulents, with both stem and leaf succulence, and
- annuals (sometimes biannuals), which become quite rare at high elevations.

The remaining two life-forms are cryptogams, that is, desiccation-tolerant, nonflowering plants:

- bryophytes ("mosses"), in some areas also ferns and lycopods, and
- lichens (including fruticose, foliose, and crustaceous).

These life-forms, in mixtures of varying abundance of each, compose the "alpine vegetation." In addition, algae and fungi play an important role. The diversity of plant structures is further enhanced by various modes of clonal propagation, which become increasingly important as elevation increases. The following is a short list of the diversity of clonal structures (Figure 3):

- tussock graminoids
- stoloniferous graminoids
- mat- or cushion-forming forbs
- stoloniferous or rhizomatous forbs
- creeping dwarf shrubs
- prostrate dwarf shrubs
- viviparous plants
- accidental clonal plants (fragmentation by external forces)

These typologies do not account for plant height or degree of horizontal spreading, both of which vary considerably among species and microclimates. Overall, the diversity of plant stature in the alpine life zone is perhaps nearly as large as the taxonomic diversity (see Halloy and Mark, 1996). It is obvious that these structural features are significant functional attributes, strongly associated with microhabitat preference and microhabitat tolerance.

Figure 3 Diversity of clonal growth in alpine plants. The examples shown here include (a) graminoid tussocks, (b) cushions with adventitious roots and potential later fragmentation, (c) mats of rhizomatous forbs or graminoids (d) mats of proliferating forbs that retain a primary root (e) stoloniferous plants, and (f) "viviparous" plants producing bulbils or floral plantlets. Reproduced from Hartmann H, from Körner Ch (2003) *Alpine Plant Life*. Heidelberg, Germany: Springer.

Diversity of Physio-types

The term physio-type is used here to circumscribe the physiological attributes of alpine plants, which may be as diverse as the variety of life-forms. Certain morphological attributes are functionally linked to physio-types. The following is only a brief summary. Readers with an interest in this field will find an extended treatment of the subject in Körner (2003).

Rates of plant photosynthesis, how photo-assimilates are invested in the plant body, nutrient use, water relations, stress resistance, and secondary metabolites all vary substantially among alpine species. The predominance of physical limitations to growth, particularly at the uppermost limits where plants can grow and survive, may be expected to narrow the spectrum of possibilities, in the ultimate case by permitting only one way to survive. Surprisingly this is not so. Even in habitats that by all standards can be rated as "extreme," one can find a suite of physio-types (often associated with specific morpho-types). This is a most important point for the study of alpine plant adaptation. The selection of a single species for study inevitably will produce data with no generalization potential. "The alpine physio-type" does not exist. One randomly selected species or small group of species may represent a very special case, and be all but "typical."

A good example is the way plants invest in biomass. Although this finds expression in morphology, the quantitative aspects of it are directly related to plant metabolism. Plants may favor roots, stems, storage organs (all three are net sinks for carbon), or leaves (the net source of carbon). How plants invest is key to the understanding of whole-plant carbon balance and

to growth and reproduction. Co-occurring species, equally successful in terms of abundance and often found together in the same habitat, may represent the left and right tails of a frequency distribution of these traits at a common attitude (Figure 4). There seems to be a multitude of ways to cope with the demands of life conditions even at extremely high elevations.

Another example is the way alpine plants construct their leaves in terms of leaf dry matter investment per unit leaf area. “Expensive” (thick) leaves contain a lot of dry matter per unit leaf area, whereas “cheap” (thin) leaves contain little. Again the diversity of this trait expressed as “leaf mass per area” (LMA, or its reciprocal specific leaf area, SLA) is very large. There is nothing like a typical alpine SLA (Figure 5; for a full account of such leaf traits in a global comparison see Körner *et al.*, 1989). The same applies to leaf nitrogen concentration and mobile carbohydrates, although there are slight overall trends with increasing elevation for SLA to decrease and nitrogen and mobile carbohydrate concentrations to increase (leaves becoming more “expensive”). However, such means

across many species need to be treated with care, given the great diversity. It cannot be concluded that alpine plants have lower SLA when a substantial fraction of all studied alpine species does not fit this pattern. The species from different elevations that are included or excluded from such community subsamples will always affect the mean.

The same applies to any other physiological trait that has been studied in more than one species. For example, freezing resistance varies enormously in alpine plant species. According to Larcher, some species can survive any low winter temperature that could occur on Earth (less than -70°C), and others are killed by only -12°C . Freezing resistance is one of the few traits where this diversity of responses could be explained by habitat characteristics, in this case the predictability of snow cover in winter. But for most other traits such clear-cut causal links have not been found. It rather seems there are many different ways to cope with similar problems. These different traits may be “nonfunctional” in the sense of not being critical for survival and reproduction under “normal” situations, but some may become decisive under very specific and rare

Figure 4 Frequency distribution of leaf mass ratio (LMR; the fraction of leaf dry matter versus total plant dry matter) in the Alps and the Andes. In the Alps, for instance, co-occurring species are found in the left (*Ranunculus glacialis*) and right (*Cerastium uniflorum*) tails, reflecting the great diversity of plant dry matter investment even at extremely high elevations. The same is true for any other mountain region, including the example for Argentina shown in the right diagram. Modified from Körner Ch (2003) *Alpine Plant Life*. Heidelberg, Germany: Springer.

Figure 5 Frequency distribution of specific leaf area (SLA) in alpine species in the Alps and the Andes. Reproduced from Körner, *et al.*, 1989.

conditions through which they might have been selected for as advantageous (see the discussion of the ecological function of diversity in Potential Functions of Alpine Biodiversity).

Diversity of Reproduction

Recruitment *via* seed is rather risky in alpine environments because the seedling needs to establish in an often short season and on a potentially hostile substrate. Hence the most common strategies for alpine plants to survive and persist are long life and clonal propagation. The production of seed itself does not seem to be a problem and alpine plants produce lots of viable seed in most years, as has been known from the beginning of alpine plant research in the nineteenth century (see review by Körner, 2003). For a functional understanding of alpine biodiversity, seed production is very important, as rare as successful seedling establishment might be. It is through sexual reproduction that the genetic diversity is retained and by which the ecotypic differentiation of traits, essential in the fragmented and ever-changing alpine environment, develops. The most important pollinators are flies; at lower alpine elevations, bumblebees, solitary bees, and butterflies become more prominent (with decreasing importance by order; a detailed analysis for the southern Andes was done by Arroyo). Roughly one-fourth of alpine plant species are wind pollinated (such as Poaceae, Cyperaceae, and Polygonaceae).

Current evidence suggests that outbreeding is the dominant form of sexual reproduction, but most alpine plants can also self (which secures some seed production if pollen transfer fails because of bad weather), and some are even obligatory selfers. The most extreme forms of retaining the parental genome is apomixis, where embryos are genetic copies of the source plant. Surprisingly, both clones and apomicts exhibit high intraspecific genetic diversity, indicating that sexual reproduction also occurs in such plants. Through genetic fingerprinting (a recent review by Witte and Stöcklin, 2010), it was shown that some of these obligatory clonal alpine plants can produce very large genetets and be thousands of years old, but clones of different genetets were often found to be intermingled. Yet clonal propagation must not be seen as a substitute to sexual propagation. Both the sexual and clonal modes occur simultaneously for most of the time. There is no indication of genetic depauperation within species with increasing elevation, but this is a field that needs more research. Current knowledge does not suggest that alpine plant diversity is limited by reproductive constraints.

It is well established through classic transplantation experiments in California, the Rocky Mountains, and the Alps that ecotypic differentiation does occur among populations from different elevations, so that genotypes of the same species from high elevation differ in stature, phenology, and physiology from lower-elevation genotypes when grown in a common garden (see review by Clements *et al.*, 1950). Hence, in addition to species diversity, discussed next, there is also a high degree of within-species diversity.

Taxonomic Diversity

The total alpine flora of the globe consists of approximately 8000 to 10,000 species of flowering plants (Körner, 2003).

These belong to about 100 (± 10) families and 2000 genera. Hence, one-fourth to one-third of all plant families of higher plants have representatives in the alpine life zone. Assuming a total known global flora of 250,000 species, alpine species contribute about 4% of the global plant species diversity. Given that only 2.6% of the global land area outside Antarctica falls in the alpine zone, global alpine plant diversity per unit land area is in fact higher than the global mean of all other biomes. Although such gross means need to be treated with great caution, one can at least conclude that plant species diversity in the alpine life zone is comparatively high, in view of the generally less luxurious life conditions found there.

Whether high mountains are biodiversity hot spots (Barthlott *et al.*, 1996) is a question of scale. The preceding numbers strictly refer to the alpine life zone as defined in the section The Alpine Life Zone. If one selects a census area that includes the full spectrum of elevations (e.g., a cross section through a whole mountain range), it may encompass almost all life zones on Earth from humid tropical forest at the bottom to glacier forefields at the top. High mountains, those in tropical latitudes in particular, indeed represent an incredible compression of biomes. Climatic and vegetation zones separated by several thousands of kilometers at sea level may be found within 50 km or less horizontal distance on the flanks of the major subtropical or tropical mountain systems. However, the topic of life zone compression in mountains exceeds the frame-work of this article, which is restricted to the discrete alpine part of mountain vegetation.

A single mountain system such as the Rocky Mountains, the Alps, the Caucasus, the Venezuelan part of the Andes, or the mountains of New Zealand commonly has an alpine flora consisting of 600 to 1500 species. This needs to be considered in view of a total flora of the arctic tundra of about 1000 to 1500 species (depending on how sub-species are ranked). In this respect, biodiversity of the alpine life zone is outstanding. A distinct mountain region such as the Teton Range in Wyoming, the Snowy Mountains of Australia, or the central part of the Swiss Alps commonly contains roughly 200–400 alpine species, a number that is surprisingly constant across the globe (most ranges harbor around 250 species). On a single sample plot (e.g., 100 $\times$ 100 m) one may find one-third of the total regional flora. An analysis of the Swiss Alps by Wohlgemut revealed that alpine plant species diversity increases with the size of the observation area up to 20 km², but beyond that species numbers level off.

Plant species diversity generally decreases with increasing elevation (Figure 6a), although there may be intermittent peaks where two altitudinal life zones merge. Again this is a question of scale. The decline of species diversity is particularly impressive in the uppermost part of the alpine life zone (Figure 7).

The diversity of cryptogams, mosses and lichens in particular, is relatively high in the alpine life zone. Species numbers may be of the same order of magnitude as for vascular plants, depending on humidity. With greater humidity one generally finds higher numbers of cryptogams. In some parts of temperate zone and subarctic mountains the biomass of fruticose lichens in alpine grassland is double that of higher plants. Since mosses and lichens are desiccation tolerant, they can occupy bare rock and scree and are among the first organisms to initiate humus accumulation on raw substrates.

Figure 6 Altitudinal trends in species diversity of higher plants in the Alps ((a) after Theurillat JP and Schlüssel A) and bryophytes ((b) after Geissler P and Velluti C). Adapted from Körner Ch (2003) *Alpine Plant Life*. Heidelberg, Germany: Springer.

Figure 7 Altitudinal trends in plant species diversity in the uppermost range of higher plant life in the Alps. Reproduced from Grabherr G, from Körner Ch (2003) *Alpine Plant Life*. Heidelberg, Germany: Springer.

Although cryptogams have almost no elevation limits as long as there is some bare substrate (rock lichens are reported at 7200 m elevation in the Himalayas), the number of cryptogam species also declines with greater elevation, as is shown in **Figure 6b** for bryophytes.

Besides the major role of microhabitat diversity discussed earlier, there are also historical reasons for alpine plant diversity. While the lowland flora changed owing to global

climatic changes, such as after the ice ages, a fraction of the then cold-adapted lowland flora migrated to high elevations and enriched the existing older stock of alpine species. This is how the edelweiss (*Leontopodium alpinum*) became a recent addition to the alpine flora of the Alps when the ice retreated. Agakhanjanz and Breckle (1995) suggested that in some mountains (e.g., the Pamirs) tectonic uplift matched time constants of speciation and contributed to the autochthonous species richness.

In summary, the alpine life zone is rich in plant species that belong to a multitude of morphological, physiological, and reproductive types and that inhabit a broad spectrum of microhabitats, reflecting both historical and even geological events. Because alpine plants are small, species diversity may exceed 50 species per 1 m² of land area, which is among the highest in the world. Alpine plants also provide a varied diet of food for alpine animals and microbes, the diversity of which will be briefly touched on in the following section.

Diversity of Alpine Animals and Microorganisms

Animal Diversity

The great variety of animals from mites to birds, and the greater fragmentation of expertise in animal sciences, may explain why there has been no attempt at a global synthesis of animal diversity in the alpine life zone. Franz (1979), in his German book on high mountain ecology, referred to a great number of otherwise scattered observations, and Meyer and Thaler (1995) attempted a summary for invertebrates, with a focus on the Alps. The following brief account leans heavily on the latter publication.

The only resident vertebrates in the uppermost part of the alpine zone (often called the nival zone) are voles, with the record finding by Halloy at ca. 6000 m elevation at a geothermic vent on Sucompa volcano in the Argentinean Andes. Snow voles are very abundant and active even above 3200 m in the Alps. At these elevations birds are visitors, but only a few hundred meters lower they are resident as the plant cover becomes more regular. In the Argentinean Andes, ducks breed at 4250 m elevation (personal observation at an alpine lake in the Cumbres Calchaquies). Snakes, lizards, and frogs are reported to occur up to 1000 m above treeline. Large mammal grazers (e.g., ibex in the Alps and guanacos in the southern Andes) occur at almost any alpine elevation, except for peaks surrounded by glaciers or inaccessible cliffs. These grazers profoundly influence the development of alpine plant diversity. In the lower and middle alpine belts, wild herbivores have been replaced by domestic herbivores in many areas (sheep, goats, yaks), which continue to exert selective pressure on vegetation. Some of these animals graze the highest fragments of vegetation, as was reported for yaks, which were found grazing above 5000 m in the dry part of the Himalayas (Miehe, 1997).

Quantitative data for some important groups of invertebrates have been compiled by Meyer and Thaler (1995). The major losses of taxonomic groups as elevation approaches the upper limits of closed vegetation are those of earthworms, gastropods, grasshoppers, Hymenoptera, and beetles (**Figure 8**), with the latter showing the greatest decline

Figure 8 Examples of elevational trends in invertebrate species diversity in the Alps. Reproduced from Meyer E and Thaler K (1995) Animal diversity at high altitudes in the Austrian Central Alps. In: Chapin FS III and Körner Ch (eds.) *Arctic and Alpine Biodiversity: Patterns, Causes and Ecosystem Consequences*, pp. 97–108. Heidelberg, Germany: Springer.

already below treeline. By contrast, flies, spiders, and springtails remain quite abundant (at 300 m above treeline, one-fifth of the total regional number of 200 springtail species were found in the Tirolian Alps). According to Swan, a salticid spider species was collected in the Himalayas at an altitude above any plant growth, possibly living on the aerial import of small arthropods from lower elevations. Only 2% of the 400 species of spiders of the central Alps of Tirol (Austria) are regularly found in the uppermost alpine zone. The more open vegetation becomes, the more invertebrate life is linked to the occurrence of compact plant forms, such as cushion plants.

In their overview, Meyer and Thaler noted that among invertebrates the herbivore species numbers declined more rapidly than species numbers in higher trophic levels. The reduced species number at “extreme” habitats is often balanced by greater individual densities per species. Overall, animal species diversity in the alpine life zone follows similar elevational trends as in plant species diversity, but in terms of the total numbers of alpine species, animals may exceed plants by factors of five to 10 (this is a personal guess). Establishing such diversity ratios would be an important contribution to the understanding of alpine biodiversity in general.

Microbial Diversity

As the altitude above treeline increases, animals make a smaller contribution to plant litter decomposition and soil formation and microbes become more important, even as their species numbers decline steadily. Diversity of soil fungi decreases with altitude and mycorrhization, the important plant root–fungus symbiosis, also decreases (Figure 9). All known types of mycorrhizae occur in alpine soils: ectomycorrhizae (e.g., on *Salix*, *Dry as*, *Polygonum*, and *Kobresia* spp.), ericoid mycorrhizae (*Ericaceae*), vesicular–arbuscular (VA) mycorrhizae (most forbs, grasses, and some sedges), and even orchid mycorrhizae. Nonmycorrhizal plant species can also be found (Gardes and Dahlberg, 1996). So-called

Figure 9 Elevational trends in mycorrhizae occurrence in the Alps. Reproduced from Haselwandter K and Read DL, from Körner Ch (2003) *Alpine Plant Life*. Heidelberg, Germany: Springer.

arbuscular mycorrhizae (Glomeromycota) and dark-septate hyphae type species (belonging to Ascomycota) are found even in the highest rock and scree habitats, though at greatly reduced abundance (for references see Körner, 2003). Yet, even completely isolated plants above 3000 m in the Alps were found with intense mycorrhization (reported by Oehl; see Körner, 2011).

The most robust of all organisms, the bacteria plus some unicellular fungi, retain a high diversity and abundance in the alpine life zone. Schinner and coworkers isolated 130 different strains of microorganisms in alpine environments of the western and eastern Alps that can survive and multiply at 0 °C. Of these, 77% were bacteria, 20% yeasts, and only 3% hyphal fungi. A very detailed analysis of bacterial diversity on Niwot Ridge, Colorado, by Mancinelli showed that *Pseudomonas* and *Bacillus* were the most abundant genera. Dinitrogen-fixing as well as nitrifying and denitrifying bacteria are abundant in alpine soils. Bacteria have no altitudinal limits as long as some organic dust and short spells with liquid water occur, and Swan reported a number of taxa isolated from substrate collected at 8400 m altitude on Mt. Everest, the environment on Earth that he thinks is most comparable with that of Mars.

Taken together, these observations indicate that mycorrhizae are a common element of alpine plant life, being more prominent in lower alpine elevations and in infertile soils and becoming rare only with isolated plants on high mountain peaks, where soils have little carbon. Rich bacterial life is found even at the highest elevations, indicating a capacity for metabolism under the most extreme conditions.

Potential Functions of Alpine Biodiversity

Among the theories that attempt to explain the functional significance of organismic diversity, the insurance theory seems to be most relevant for the alpine life zone. In simple terms it says that a species-rich, functionally partly redundant

organismic “work force” ensures the functional integrity of ecosystems even if some of the organisms die out. A complete loss of species by extreme stress or through pathogens would be nearly irreversible in steep alpine terrain, because it is the presence of at least some species that prevents the soil from being washed away. The sustained functional integrity of alpine ecosystems is inevitably tied to the presence of soil, and this presence is inevitably dependent on the roots and rhizomes that hold it. Strong-rooted plants are the keystone elements for the preservation of the alpine ecosystem in steep terrain. A high diversity of species is commonly associated with a high diversity of rooting patterns, which in combination create the mechanical strength required to hold the soil (Pohl *et al.*, 2009).

Messerli and Ives estimated that 10% of the global human population depends directly, and 40% of the population indirectly, on mountain ecosystems, and thus the stability of their upper part, the alpine zone, is of critical significance to society (Körner and Ohsawa, 2006). Supplies of drinking and irrigation water, as well as the safety of hydroelectric schemes and transport routes, depend on intact upslope soil conditions, and alpine biodiversity helps to ensure ecosystem health. Of course alpine biodiversity also provides other things. Alpine meadows and fellfields are very attractive landscapes for human recreation, and with their high biodiversity they are of prime conservation value; in many regions they represent the last undisturbed natural areas. Because the alpine life zone is represented across the globe, it is also ideally suited for global monitoring of biological responses to atmospheric change.

Alpine Biodiversity and Global Change

Global change has many facets, all related to the ever-increasing use of resources and land area because of human population growth and the increasing consumption of goods. The most severe impacts on alpine ecosystems are (1) land use practices (2) potential global warming with associated changes of snow cover and permafrost, and (3) increasing wet nitrogen deposition. Other aspects of global change, such as atmospheric CO₂ enrichment by itself, increasing ultraviolet radiation due to ozone layer depletion, and air pollutants other than nitrogen loading, seem to be of minor significance on a global scale (see review by Körner, 2003).

Land use, in particular the intensification of pasturing or the reverse, the abrupt abandonment of former, traditionally pastured alpine terrain, exerts the greatest influence. The steeper the terrain, the more critical these effects become. Overgrazing generally diminishes plant diversity and ruins the protective plant cover within a few seasons, with self-repair of the ecosystem commonly occurring at a much slower rate than soil erosion. In contrast, moderate and well-managed grazing can increase biodiversity and create short and dense swards of vegetation that are extremely robust against erosion and increase catchment water yield. Some of the biodiversity hot spots of the Alps, the Caucasus, and the Himalayas are traditional pastures in the lower alpine belt. There is no way of maintaining these systems by “let alone” grazing strategies, because herds of domestic animals tend to crowd certain areas and ignore others. Maintaining these intact alpine grasslands

Figure 10 (a) Species responses to climatic warming. Mountains may be refugia (2, 4), traps leading to local extinction (3, 5), or a chance to escape climate warming by topography effects (6). Lowland species often have to move greater distances (1). (b) Upslope migration of species or niche filling? Both responses are likely with climatic warming and will alter local species abundance. Niche filling, that is, “horizontal reallocation,” will precede longer-term changes of the position of whole vegetation belts.

is very important for at least three reasons: (1) their often very impressive biological richness, (2) their continued potential as a “clean” food source, and (3) their positive influence on water yield. The abrupt abandonment of pastures leads to an unstable transition phase that may last for a century before new, well-adapted communities of species are able to return. A later reversal back to the previous biodiverse pasture-land is often impossible within a reasonable time and with affordable effort, because the biological structure and the soils of these pastures took many hundreds or thousands of years to develop, but are rapidly converted.

Climate warming will affect alpine biodiversity in subtle ways because of the great variety of intermingled microhabitats (see Habitat Diversity, a Key to Alpine Plant Diversity). Although a number of authors documented some upslope migration of species, the more important changes possibly happen among microhabitats, with new niches filled by species and other niches abandoned (Figure 10; Scherrer and Körner, 2010). These mosaics of life conditions represent a certain margin of safety against the loss of alpine species in a slightly warmer overall climate. However, the abundance of species will change as the abundance of their microhabitats changes. Effects on snow cover and snow duration will be more critical than temperature *per se*. Exceptions to these scenarios are mountains that are not high enough, in which case the current alpine biota will find no upslope escape if it gets warmer.

Since alpine vegetation is well adjusted to cope with low soil nutrient levels, the regional increase of soluble nitrogen deposition will influence biodiversity. More vigorous and nitrogen-demanding species are likely to gain space over slower-growing, smaller species. Since these more vigorous species are commonly also less resistant to stress, nitrogen deposition can increase the sensitivity of certain ecosystems, while others (e.g., pioneer vegetation) may profit. It was shown that even minute additions of nitrogen fertilizer – less than is contained in many places in lowland rain-water – can create drastic changes in the alpine flora (Körner, 2003).

In summary, the greatest risk of loss of biological diversity in the alpine life zone is human land use. However, land use can also contribute to the maintenance of highly diverse and stable ecosystems in the lower alpine belt if sustainable management practices are applied.

Glossary

Caatinga Within the Amazon region this is applied to open forest on white sand, which occurs in the basin of the Rio Negro. The term is also applied to the semidesert region of northeast Brazil; it is an indigenous word from the Tupi language meaning an open place.

Capoeira Brazilian term for secondary forest on cleared ground.

Cerrado The Brazilian term for the large area of savanna and savanna forests that are the dominant vegetation of the Planalto of Central Brazil.

Igapó Vegetation periodically flooded by acidic black water or clear water rivers.

Llanos The term used in Colombia and Venezuela for the extensive grass-dominated, open savannas of the orinoco river region.

Inselberg Granitic domes that rise above the forest in the older geological formations to the north and south of the alluvial plains of Amazonia and elsewhere.

Rivers in Amazonia The three main types of rivers in the Amazon region are known as white, black, and clear water. White water rivers are muddy with much suspended sediment and are neutral or only slightly acidic. Black water rivers are dark because of dissolved tannic matter and are acidic (pH about 4). Clear water has neither mud nor humic matter and is usually slightly acidic.

Tepui Venezuelan term for the sandstone table mountains of the Guayana Highland or Lost World region.

Terra firme Brazilian term for areas that are above the level of periodic inundation by the rivers.

Várzea Brazilian term for vegetation periodically flooded by white water rivers.

Most people think of the Amazon region as being covered by a uniform green carpet of rain forest. This is far from reality, because Amazonia is a complex mosaic of ecosystems varying from typical tall rain forest to open grassland savannas to scrubby vegetation on white sand that resembles the chaparral of western California. Even when one type of vegetation is studied, many local variations occur depending on local edaphic conditions, the flooding regime, or rainfall. This great variety of ecosystems has been defined in different ways by different authors depending on their approach to the subject. For example, some authors have concentrated on the physiognomy and structure of the vegetation (Hueck, 1966; Ducke and Black, 1953; Prance, 1987) and others, such as Holdridge (1972), on the life zones that define vegetation based on climatic factors such as rainfall, temperature, and altitude. In this account, the primary separation of ecosystems is based on floristics, that is, the individual species that make up an ecosystem, and on their physiognomy and structure.

In addition to the previously mentioned factors that account for the variety of ecosystems, the history of the region must also be taken into consideration. Over time the Amazon ecosystems have by no means been stable. The distribution of the different types of vegetation has fluctuated with changes in worldwide climate. The distribution and species composition of forest and nonforest biomes changed continuously during the Pleistocene and earlier epochs. What today is continuous forest was once broken up into isolated blocks interspersed with deciduous forest and savanna ecosystems that later coalesced when the climate again became favorable for forest. These changes have added to the overall complexity of the current Amazon ecosystems. The principal vegetation formations are described here.

Nonflooded Terra Firme Ecosystems

The primary division of Amazonian ecosystems is between those that are subject to periodic flooding by the seasonal rise and fall of river water levels and those that are above the flood level. In Brazil the nonflooded land is known as terra firme, and since this term is widely applied in the literature about Amazonian vegetation it is also used here. Within the Amazon region there are forests and savannas on both terra firme and floodplain.

Rain Forest on Terra Firme

This is the single most widespread vegetation type of Amazonia and covers approximately 50% of the region. Rain forest occurs where there is heavy rainfall, usually greater than 2000 mm y⁻¹ that is not markedly seasonal. Some of the other types of vegetation described here occur in areas with a marked dry season or with less rainfall, for example, on the southern fringes of Amazonia where transition forest and semideciduous forest occur.

The rain forest on terra firme is characterized by its dense closed canopy at about 25–35 m above the forest floor. Above the canopy a number of tall emergent tree species rise up to about 50 m. The dense canopy means that little light (about 3%) penetrates to the forest floor and the herbs and shrubs growing there are adapted to living in low light. The periodic sunflecks are of considerable importance to those species and to the seedlings of trees. Tree species range from light demanders that grow quickly where light is abundant, but that survive poorly in shade, to shade-tolerant species whose seedlings can survive and grow in low light (Pires and Prance, 1984).

Rain forest on terra firme is most notable for its amazing diversity of tree species. There have now been numerous inventories of trees in different parts of Amazonia. The highest number of trees of 10 cm diameter or more was recorded in western Amazonia at Cuyabeno in Ecuador, where Valencia *et al.* (1994) found 307 tree species on a single hectare. Inventories have listed from 81 to 307 species depending on the soil, rainfall, and the seasonality of the climate (Table 1). When the total number of woody species in a hectare is counted, there can be as many as 550 species.

A summary of the α -diversity of the terra firme forest is given in ter Steege *et al.* (2003) based on 275 one-hectare plots from all over the Amazon region. These authors found that dry season length, while only weakly correlated with average tree α -diversity, is a strong predictor of tree density and of maximum tree α -diversity.

The floristic composition is not uniform and some species have very local distributions. As a result, the lowland forest of

Amazonia has been divided into a number of distinct phyto-geographic regions based on the distribution of species. The first important subdivision of the region was offered by Ducke and Black (1953): this was later modified slightly by Prance (1977). The seven major phyto-geographic regions can be explained by the history of the region and by the present-day climate. For example, the Atlantic coastal region has a wet almost aseasonal climate, but farther inland around Santarém, Brazil, there is a region with a much drier climate and a strong dry season. Farther to the west near the Andes in Peru, the climate is much wetter and less seasonal. Each of these regions falls into different phyto-geographic zones (see Daly and Prance, 1989, for a review).

Figure 1 shows the phyto-geographic regions with the distributions of some plant species superimposed. While some species have extremely restricted local ranges and help to define the different regions, others are widespread and occur throughout the entire region, for example, *Caryocar glabrum*,

Table 1 Results of some 1-ha inventory plots in the Amazonian rain forest where trees of 10 cm diameter or more were counted

Site	No. of species	No. of trees	Habitat
Cuyabeno, Ecuador	307	693	Aseasonal rain forest
Yanomono, Peru	283 (+ 17 lianas)	583	Aseasonal rain forest
Cocha Cashu, Peru	189	650	Seasonal rain forest
Xingu River, Brazil	162	567	Seasonal rain forest
San Carlos de Rio Negro	83	744	Aseasonal forest on poor oxisol
Beni, Bolivia	94	649	Seasonal forest

Figure 1 Map showing the phyto-geographic divisions of the Amazon rain forest as defined by Prance (1977). The symbols represent the distributions of some species of trees typical to each region. L = *Licania* (Chrysobalanaceae), H. = *Hirtella* (Chrysobalanaceae), Esc = *Eschweilera* (Lecythidaceae).

Licania heteromorpha, and *Parinari excelsa*. The distribution of individual species is also dependent on altitude, soil, drainage, and topography, as well as climatic factors. There is not much structural or physiognomic difference in terra firme forest between the different phytogeographic regions, but the canopy height can vary considerably from one place to another.

Between 1972 and 1983, the RADAMBRASIL project surveyed the entire Brazilian Amazon using side-scanning radar. It distinguished two main types of forest on terra firme based on topography: forest in the lowlands on relatively flat ground and hill forest on undulating land between 250 and 700 m. The dense lowland forest occurs mainly on the area of Tertiary and Quaternary sediments between the major rivers on land below 250 m. This forest usually has a canopy at about 30 m and frequent emergent trees up to 50 m, for example, the Brazil nut (*Bertholletia excelsa*) or the angelim pedra (*Dinizia excelsa*), the largest tree in the forest. The understory has relatively few shrubs and consists mainly of young individuals of canopy tree species. Above 250 m the lowland forest tends to be replaced by hill forest, which has a lower canopy and its emergents reach to about 35 m tall. The canopy is more open and consequently the understory is often much thicker and has a greater diversity of shrubs and herbs. The physiognomy of hill forest is far more varied than that in lowland forest, and there are often marked differences between slopes and valleys in both physiognomy and species composition, adding to the total species diversity of the region. Much of the variation in composition of terra firme forests is related to edaphic conditions. A study across a 750 km transect of terra firme forest in western Amazonia indicated two sharp discontinuities in community structure at the genus level (Pitman *et al.*, 2008). This variation is congruent with a change in soil texture due to a subterranean paleoarch. A second discontinuity is noted between clay and white sand soils.

Most trees of the terra firme forest have large heavy fruit or seeds that drop to the ground. After this initial dispersal by gravity they are often carried farther by secondary dispersal agents such as rodents and other terrestrial animals. In contrast to savanna and riverine vegetation, most terra firme forest species are not adapted to long-distance dispersal. This must affect the rate of expansion of the forest into potentially colonizable habitats following climate change or human-caused forest destruction. The various species of primates in the canopy are important dispersers of seeds as well as seed predators.

White Sand Oligotrophic Formations

The edaphic factor that has the most striking effect on vegetation on terra firme is white sand soil. This habitat is scattered throughout the region, but especially between the Rio Branco and the Rio Negro in Brazil (Figure 2). These areas are characterized as podzols, or leached pure white sand, known as regosols in Brazilian soil terminology. The origin of these sands is either from the erosion of sandstone mountains in the northern part of Amazonia or from uplifted former river or sea beaches throughout the region. This soil is nutrient deficient and, as a consequence, has a distinctive lower vegetation that varies from an open savanna-like formation to low forest.

In the Old World tropics this is called heath forest, but a variety of local terms have been applied in the Neotropics, such as Amazonian caatinga, campina, campinarana, chavascal, and charravascal. The commonest term for campina forest in Amazonia is caatinga, but this leads to confusion because the same term is used for the semidesert thorn-scrub of northeastern Brazil.

The largest area of campina forest in the upper Rio Negro region has a canopy at about 18 m. The trees tend to be of a much smaller diameter than in terra firme forest and the branching is tortuous and does not form a closed canopy. As a result, the ground vegetation is abundant and rich and it contains many endemic species, especially in the families Bromeliaceae, Marantaceae, and Rapateaceae. There are also abundant epiphytic Orchidaceae, Araceae, and pteridophytes on the tortuous branches of the trees.

In addition to the almost continuous area of campina forest in the upper Rio Negro, there are many small isolated patches of campina especially in the lower Rio Negro around Manaus. These form small islands of campina surrounded by forest on terra firme. Some of the species that dominate these campina islands are *Aldina heterophylla*, *Humiria balsamifera*, and *Pradosia schomburgkiana*. These campina islands have trees with particularly tortuous branches that are heavily loaded with epiphytes. Besides the epiphyte families mentioned earlier, Gesneriaceae and *Peperomia* in the Piperaceae are common and they support ant gardens where ants nest among the roots and form a rich layer of detritus and disperse the seeds. In some campinas there are open areas where bare sand occurs that is often covered by the blue-green alga *Stigonema tomentosum*, as well as small islands of shrubs and low trees with abundant lichens around them. There is good evidence from the presence of pottery shards that these open areas were cleared by indigenous peoples about 800 years ago. The recolonization by vegetation has been extremely slow because of the lack of nutrients in the soil, and so many open patches still remain today. Often associated with areas of white sand are areas of black soils (*terra preta*) of anthropogenic origin (see Glaser and Woods, 2004). The vegetation on these soils tends to be much richer (Paz-Rivera and Putz, 2009). The black soils are being overexploited for agriculture and use in horticulture.

A study of a campina island near Manaus showed that three-fourths of the species of trees and shrubs are adapted to long-range dispersal by birds, bats, or wind. Therefore, campina species tend to have a much greater capacity for long-distance dispersal than species of the terra firme forest.

White sand areas occur in many other places throughout Amazonia. One large area is that of Serra do Cachimbo on the border between the Brazilian states of Pará and Mato Grosso. This area has a similar physiognomy to the campinas of the Rio Negro, but the species composition differs considerably and there are a number of species that are endemic to the sands of Cachimbo. To the west of this region there are white sand areas in Amazonian Peru and Colombia and in the Brazilian state of Acre. In the Guianas, white sand areas are abundant and are covered by forest or by open savanna. Dense forests on white sand in Guyana are dominated by the legume species *Eperua falcata* and two other species of *Eperua* and are termed wallaba forest. To the south of Amazonia there are

Figure 2 Map of northern South America, showing principal cities and rivers and localities mentioned in text.

extensive areas of white sand vegetation in the Chapada de Parecís in Rondônia, where many of the same genera occur as in the Rio Negro region, for example, *Abolboda*, *Clusia*, *Humiria*, *Paepalanthus*, *Retynophyllum*, *Ternstroemia*, and *Xyris*.

The other white sand formation that occurs in Amazonia is called restinga. This low scrub habitat along the seacoast of Brazil is found on sand dunes beyond the influence of salt water and inland from beaches or mangrove forest. Within Amazonia, restinga is not extensive but it extends southward around the coast to southern Brazil. Restinga is a rather uniform scrub characterized by the presence of *Chrysobalanus icaco*, a species that also occurs in similar habitats in West Africa. Common herbs include the ubiquitous *Ipomoea pes-caprae* and the sedge *Bulbostylis capillaris*; shrubs include *Hibiscus tiliaceus* and *Manilkara triflora*.

Dry Semideciduous Southern Fringe Forests and Cerradão

This formation occurs predominantly in southeastern Amazonia on the border with the cerrado (the savanna) of the Central Brazilian Plateau. This type of dry forest also extends into the cerrado region, where it is termed cerradão. In this region the climate is much more seasonal, drier, and less

humid. As a result, the trees lose some of their leaves in the dry season to make the forest semideciduous in marked contrast to the evergreen terra firme forest. Dry forests occur in small patches and do not occupy an extensive area. A small amount of dry forest also occurs in northern Amazonia in Roraima state and in southern Guyana. The dry forests really form part of the transition zone between Amazonian high forests and regions of savanna and are interspersed with the various types of transition ecosystems described in the following section. [Ivanuskas et al. \(2008\)](#) suggested that the transition forests of the upper Xingu river region be given a distinct phytogeographic recognition as "Evergreen Seasonal Forest." This was markedly distinct in their analysis based on physiognomy, floristic composition as well as edaphic factors.

The semideciduous forest is not rich in endemic species. Some of the common species that are widespread and characteristic of this formation include *Bowdichia virgiloides*, *Centrostigma macrophyllum*, *Combretum leprosum*, *Erythrina ulei*, *Lafouensia pacari*, *Magonia glabrescens*, *Attalea speciosa*, *Physocalymma scaberrimum*, and *Vochysia haenkiana*.

A study of an area of this type of forest in southern Amazonia at Sararé in Mato Grosso found that it contained many species typical of Amazonian terra firme, such as *Enterolobium schomburgkii*, *Hernandia guianensis*, *Parkia* spp.,

Schizolobium amazonicum, *Simaruba amara*, and *Spondias lutea*, mixed with others more characteristic of the forests of São Paulo, such as *Aspidosperma*, *Myroxylon*, and *Poeppigia procera*. There are also a number of species in this belt of transition forest that do not occur in central Amazonia within the dense forest region. The best known of these species is mahogany, *Swietenia macrophylla*, which occurs around the western and southern fringes of Amazonia. The genus *Myroxylon* is another example of this type of distribution. The other region that contributes to the semideciduous ecosystem is the cerrado region of central Brazil. Species such as *Apuleia leiocarpa*, *Er. ulei*, *Plathymenia foliosa*, and *Phys. scaberrimum* are typical cerrado species that extend their ranges into the semideciduous forest.

Transition Ecosystems

The transition forests form a belt of vegetation between the terra firme forests of Amazonia and the savannas of Roraima and Rupununi to the north and the cerrado of central Brazil to the south.

Transition forests mostly occur in regions with a strongly seasonal climate, but the boundary between them and the tall rain forest is not a clear-cut line. Rain forests extend farther into areas with seasonal climates that are on soils where the periodic water stress is compensated for by good water retention. This can occur because of either the physical properties of the soil or the proximity of rivers. Conversely, seasonal forests can extend into areas with little dry season in places that easily become dry, such as ridge crests and coarsely textured soils, and also on oligotrophic soils. Thus the superimposition of a climate map on that of vegetation will not necessarily correspond well and the forest boundaries are reticulate. The rain forest to seasonal forest ecotone still remains one of the least-studied ecosystems of Amazonia, yet it is in this boundary where most deforestation is occurring because of its accessibility to the developed south of Brazil and because the soil there tends to be more fertile than under evergreen forests. It is also easier to farm in a seasonal region when there is a time to burn the cut forest and to dry crops. In addition to the semideciduous forest, there are various, more specialized formations that tend to be dominated by one or a few species only. The three principal types of transition forest are described in the following.

Babassu Palm Forest

Babassu is a species of palm, *At. speciosa* that dominates the transition forests of the southeastern fringe of Amazonia in the Brazilian states of Maranhão, Tocantins, and Pará. In a babassu palm forest, the trees are widely spaced and do not form a closed canopy. The tree height is from 10 to 25 m and many pure stands of *Attalea* occur. As a result, species diversity is extremely low and there are few endemics. *At. speciosa* is a fire-resistant species and this is probably the reason for its abundance in a transition region to savanna. The fires that occur naturally in the cerrado probably help to reduce the competition from other species and allow babassu to

dominate. The extent of babassu forest has probably been increased by deforestation both historically by indigenous peoples and more recently by clearance for farming. Babassu occurs as a component of semideciduous forest, and when the latter is cleared, it is often one of the few species that survives the burning, hence the recent increase in area covered by babassu forest. Babassu is also an extremely useful species and oil is extracted commercially from the kernel of the fruit. The woody endocarp is used to make charcoal or as a fuel for factories, and the outer mesocarp is used as an edible flour.

Liana Forest

As the name implies, in a liana forest woody vines or lianas predominate. It is open forest with well-spaced trees that are often completely entwined by lianas. In Brazil this formation is known as cipoal or mata de cipó (cipó being the Brazilian word for liana). The tree species in liana forest are some of the commoner species of terra firme forest, but they occur at a much lower diversity. Babassu palm also occurs frequently in liana forest, but there is a far greater quantity of lianas here, particularly in the plant families Bignoniaceae, Dilleniaceae, Leguminosae, Malpighiaceae, and Menispermaceae. To walk through this forest, one has to cut one's way through a thicket of tangled liana stems.

Liana forest is especially abundant in the area between the Rios Tapajós Xingu, and Tocantins in southern Pará, Brazil, but it also occurs in small patches in Roraima state in the north. The exact reason for the occurrence of this type of forest has not yet been established. One study showed that the soil under liana forest did not differ from that of nearby terra firme forest. It is thought to occur in regions where the forest has been disturbed by either human intervention or natural climate cycles.

Some of the typical Amazonian tree species that occur in liana forest include *Astronium gracile*, *Astronium lecontei*, the Brazil nut (*Be. excelsa*), *Elizabetha paraensis*, and *Sapium marmieri*.

Bamboo Forests of Western Amazonia

Bamboo forest is an open type of transition forest that occurs mainly in southwestern Amazonia in Amazonian Peru, Bolivia, and the Brazilian state of Acre. In Acre, bamboo forest is abundant and covers a large area. In this forest various species of bamboo (*Bambusa* subgenus *Guadua* and the genus *Merostachys*) are extremely frequent in both the understory and the canopy, where they reach up to 30 m. Bamboo forest contains relatively few tree species and those that do occur are mostly common species of the terra firme forest. The bamboos are interspersed with trees, which lend support to their arching branches. By branching the bamboos spread far over the forest canopy and can easily be picked out in aerial photographs. Botanist Thomas Soderstrom measured a bamboo culm of 29.77 m in length with a side branch of 9.69 m and a secondary branch that was a further 4.96 m. The belt of transition forest that extends across the southern fringe of Amazonia is dominated by bamboos to the west, lianas in the central part, and babassu palms to the east.

Floodplain Ecosystems

Almost 10% of the Amazon region is subject to periodic flooding due to the rise and fall of river levels in most of the region and backup of the rivers from high tides in the delta region. River levels are very seasonal and the magnitude of change is considerable. In central Amazonia around Manaus, the Rio Negro and Rio Solimões undergo an average annual change in water level of 10 m, and the difference between extremely high flood years and the extreme low level is 15 m. The record high level at Manaus was recorded in 2009, followed by a record low in 2010. The forests beside the rivers are flooded to a depth of several meters for 5–9 months each year. The two main flooded ecosystems are those of the white water rivers called várzea and those of the black and clear water rivers called igapó (Prance, 1979).

Várzea Forest

Várzea forest is formed on soil that is flooded by the alluvial-rich white water rivers. The soils are therefore much more fertile than those of the terra firme because of the annual deposit of alluvial matter. For this reason, much of the várzea forest has been replaced by agricultural systems that are more sustainable than those on terra firme. Seasonal várzea is forest that is periodically flooded by the seasonal rise and fall of river level, and tidal várzea is flooded twice a day by fresh water as a result of backup caused by the tide in the Atlantic Ocean. There are few differences between seasonal and tidal várzea and most plant species can occur in both types.

Várzea forest is tall and is physiognomically quite similar to terra firme forest, but it is much less diverse in species. Buttressed trunks are common in várzea forest trees, and lianas are also common. The várzea often has a rich understory with a large number of species of Zingiberaceae, Marantaceae, and Heliconiaceae. In upper Amazonia the várzea forests are much richer in species composition than those of lower Amazonia. Várzea forests tend to have high riverbanks that form natural levées. Some of the typical species are *Buchenavia macrophylla*, *Ceiba pentandra* (the kapok tree), *Crataeva benthamii*, *Gustavia hexapetala*, *Hevea brasiliensis* (the rubber tree), *Hura crepitans*, *Piranhea trifoliata*, *Rhedia brasiliensis*, and *Virola surinamensis*, as well as numerous species of palms such as *Astrocaryum jauari*.

In the lower Amazon, where the river is very wide, especially between Itacoatiara in Amazonas and Monte Alegre in Pará, the várzea forest is often accompanied by large meadows of grassland known as canarana (*Echinochloa spectabile* being the dominant species). This region has narrow bands of forest on higher ground beside the rivers and extensive grass meadows on the lower, more flooded ground farther away from the river margins; the lowest areas form lakes. When the waters recede and the lakes dry up, the open ground quickly becomes covered with grass, increasing the area of the meadows. The arboreal species that are most common in this type of várzea are *Bombax munguba*, *Calycophyllum spruceanum*, *Cr. benthamii*, *Cordia tetrandra*, *Pithecelobium multiflorum*, *Muntingia calabura*, and *Salix martiana* var. *humboltiana*. The latter species of

willow occurs mainly on muddy beaches that are in the process of formation.

Igapó

The black water and clear water rivers form a very different ecosystem than do the white water rivers. In this case there is little or no sediment and the water is acid and nutrient poor. In black water rivers the water contains much humic matter. The rivers flow from either sandy or rocky terrain. The largest black water river is the Rio Negro and the three major clear water rivers are the Rios Tapajós, Tocantins, and Xingu.

In these rivers in the dry season the banks are usually gradually sloping sandy beaches with trees on them, but in the rainy season they are transformed into an inundated igapó forest where only the canopy is above water. Characteristic species include *Alchornea castaniifolia*, *Couepia paraensis*, *Exelodendron barbatum*, *Eschweilera tenuifolia*, *Neoxythece elegans*, and *Virola elongata*. Three common palms of the igapó of the Rio Negro are the piassaba, *Leopoldinia piassaba*, the closely related *Leopoldinia pulchra* and the caranaí (*Mauritiella aculeata*).

The physiognomy of the igapó forest is usually rather different from that of the terra firme and várzea forests. This forest is of a lower stature and the trees are more scattered. Many species are confined to the igapó forest but local endemism is rare. One interesting local endemic, *Polygonanthus amazonicus*, occurs on the sandy beaches near Maués in Pará, and it is still of uncertain plant classification.

Near Manaus, where the large black water Rio Negro and the white water Amazon (called the Rio Solimões above Manaus) merge, there are extensive areas of inundation forest that are influenced by both black water and white water. A study of this area showed that the floodplain forest contains a mixture of species that are characteristic of várzea and igapó as well as many of the species that are common to both ecosystems, such as *Astrocaryum jauari*, *Calophyllum brasiliense*, *Eschweilera albiflora*, *Gustavia augusta*, *Hevea spruceana*, *Pari. excelsa*, and *Vatairea guianensis*.

The seeds of both várzea and igapó species are often light and have many different flotation mechanisms, such as spongy tissue, oil bodies, hollow areas, or a light mesocarp. In some cases it is the seed that floats, and in others the entire fruit floats to ensure dispersal by the water currents, for example, in the macucu (*Ald. heterophylla*). In the rubber tree the seeds float, and in the case of *Montrichardia arborescens*, an aquatic aroid, the whole fruit floats.

Other riverside trees have a fleshy fruit that is often colored green. These are the ichthyochorous or fish-dispersed species. When the fruit of these trees falls into the river in the flood season, fish can be seen grabbing them rapidly. The local people know that they can catch these fruit-eating fish by using tree fruit as bait on their hooks. For example, the fruit of *Alc. castaniifolia*, *Carapa guianensis*, and *Astrocaryum jauari* are frequently used as bait. The seeds of most species of the igapó and várzea forest are dispersed either by water or by fish. Some of the shrubs that grow on riverbanks, such as *Myrciaria dubia* or the camu camu, *Alc. castaniifolia*, and *Couepia uiti*, produce fruit as the river level rises. The fruit become submerged and

are then readily available to their fish dispersal agents, who pluck them from the trees.

Lakes, Swamps, and Other Aquatic Systems

Lakes

Not all of the flooded ground is covered by the tall, species diverse, várzea and igapó forests. There are many lakes scattered throughout Amazonia and some of them are extensive, such as Lago Manacapuru in Amazonas and Lago Grande in Pará. In the upper Amazon in Peru and in the upper reaches of some of the main Amazon tributaries, oxbow lakes are also common.

The lakes of Amazonia have an extensive macrophyte flora. White water lakes beside the main Amazon River that are cut off from river flow in the dry season are the habitat of the world's largest water lily, *Victoria amazonica*. This spectacular plant is pollinated by scarab beetles that the lily traps inside its flowers for 24 h. There are many species of Pontederiaceae, including the water hyacinth *Eichhornia crassipes*, which has become a noxious weed in many other parts of the tropics. Another common floating aquatic in the same family is *Reussia rotundifolia*.

In most lakes the aquatic flora can be divided into the free-floating species, those that are rooted to the bottom of the lake, and those growing around the margin of the lake. In the free-floating group there are several aquatic ferns such as *Azolla*, *Salvinia*, *Ceratopteris pteroides*, and *Marsilea polycarpa*. Others include a floating spurge, *Phyllanthus fluitans*, a legume, *Neptunia oleracea*, and *Ludwigia helminthorrhiza* in the willow-herb family or Onagraceae. Some of the rooted aquatics are *Limnocharis flava*, *Pacourina edulis*, *Caperonia castaneifolia*, *Aeschynomene rudis*, *Ludwigia decurrens*, and *Sphenoclea zeylanica*. Growing around the lake margin are common species such as *Cassia occidentalis*, *Cyperus mutisii*, *Paspalum fasciculatum*, *Hyptis parkeri*, and *Diodea kuntzei*. When the lake level rises, large mats of floating vegetation, mainly the grasses *Panicum* and *Echinochloa*, are washed out into the river and can be seen floating downstream.

Permanent Swamps and Buritizal

In a few places in Amazonia the water never drains and permanent swamp occurs. The permanent swamp forest has a low species diversity and covers only a small area of the region. The soil under the forest is a eutrophic humic gley and in some areas of dystrophic humic gley palm swamp occurs. This is usually dominated by species of *Mauritia* or *Euterpe*. There are several extensive areas of *Mauritia flexuosa* palm swamp that are locally called buritizal. These occur in eastern Amazonia in the state of Maranhão, in central Amazonia in the basin of the Rio Jutai, and in the west near Iquitos, Peru. Since almost all parts of both *Mauritia* and *Euterpe* are useful, these oligarchic or one-species forests have great potential for sustainable use. *Euterpe oleracea* occurs in large quantities in the swamp forests of Marajó Island in the Amazon delta, where it is harvested extensively for both its fruit and as a source of palm hearts or palmito. *Mauritia flexuosa* also occurs in the gallery forests of the Roraima savanna and in várzea forest and is not confined to the permanent swamp forest.

Pirizal

Pirizal refers to a type of vegetation that occurs in small restricted areas of eastern Amazonia. A pirizal is a shallow lake or pond with stagnant water and a large number of rooted plants that emerge above the water. The commonest species are the large sedge, *Cyperus giganteus*, and *Thalia geniculata*, an aquatic member of the Marantaceae. There are also a number of typical floating aquatics such as species of *Cabomba*, *Eichhornia*, *Limnathemum*, *Nymphaea*, *Sagittaria*, and *Salvinia*. The *Mauritia* palm often grows around the margins. The pirizals occur as enclaves in the midst of dense forest, mainly in the state of Amapá in an area along the coast, especially in the region of Mazagão. There are also sedge-dominated communities in Amapá called cariazal. These are dominated by *Diplasia karataefolia*, the local name of which is caria.

Mangrove Forest

The mangrove forest of Amazonia occurs as a narrow littoral belt in the coastal area that is subject to salt water inundation by tidal movements. Amazonian mangrove forests are species poor and have a rather uniform formation. The commonest species is the red mangrove, *Rhizophora mangle*, which occurs in the saltiest water. *Rhizophora racemosa* occurs in less salty brackish water, and the intermediate hybrid species *Rhizophora harrisonii* occurs in the area in between. All three species are found in the mangroves of the Amazon coast.

The other common species of this formation are *Avicennia nitida*, the white mangrove, *Laguncularia racemosa*, and *Conocarpus erectus*. *Avicennia* grows inland for a considerable distance upriver into the zone of fresh water, whereas all three species of *Rhizophora* do not extend beyond the influence of salt water. In areas of clay salt beaches the small grass *Spartina brasiliensis* plays an important role in stabilizing the soil as it occurs in thick dense carpets. Some of the species that are common around the fringes of Amazonian mangrove are *Annona palustris*, *Hi. tiliaceus*, *Pithecellobium cochleatum*, *Pterocarpus officinalis* and the mangrove fern *Acrostichum aureum*. The Atlantic coastal mangrove forests of South America are species poor in comparison to those along the Pacific coast. A good review of studies of the Amazonian mangrove vegetation is given in Menezes *et al.* (2008).

Amazonian Savannas

Nonflooded Savannas and Cerrado

Scattered throughout the rain forest region of Amazonia are a number of patches of open grassland or savanna. Some of these cover small areas and others are quite extensive. The largest ones are the Roraima–Rupununi savanna in Guyana and northern Brazil, which covers 54,000 km², the Sipaliwini savanna on the border between Brazil and Suriname, the Pampas del Heath in Peru, and the Humaitá savannas in the south of Amazonas state. Amazonia is bordered to the south by the largest savanna area of South America, the cerrado of the Central Brazilian Plateau. There are also banks of cerrado that extend into the rain forest region of southern Amazonia, but the isolated Amazonia savannas are a rather different

formation from the cerrado. The Amazonian savannas have less local endemism and species diversity than the cerrado, few suffrutices (woody plants with underground branches and short aerial shoots which die back after fires and resprout), and less tortuously branched trees, indicating that fire is not as strong a factor as it is in the drier cerrado.

The cerrado region of central Brazil has an extremely well defined dry season, the air humidity is often low, and the soils are very deep. As a consequence, roots are also deep and are specialized to reach water at considerable depth when the upper layers of soil are dry. When the topsoil is scraped off by a tractor, immediately there is a large amount of sprouting from vegetative organisms such as xylopodia. In contrast, in Amazonian savannas the roots are more superficial and there are not many vegetative parts in the soil to allow vegetative reproduction. Also, the climate in Amazonia is more humid and the relative humidity of the air is higher. Furthermore, in Amazonian savannas there is never such a dense arboreal cover as in the more closed types of savanna, whereas in the cerrados, dense closed vegetation (cerradão) is common and is similar to the dry semideciduous forest. [Ratter et al. \(2003\)](#) analyzed the species composition of 376 areas of cerrado and Amazonian savannas and found that in both systems of classification that they used the Amazonian disjunct sites formed a distinct group separated from the cerrado samples.

The two ecosystems have many species in common, for example, *Antonia ovata*, *Byrsonima verbascifolia*, *Curatella americana*, *Hancornia speciosa*, *Palicourea rigida*, *Qualea grandiflora*, *Salvertia convalarioidora*, and *Tabebuia caraiba*. The wide distribution of these and other species is evidence of a historically more continuous distribution of savannas during previous periods of drier and cooler climate. However, it has been shown that many savanna species have a much greater capacity for long-distance dispersal than rain forest trees. Bird- and wind-dispersed diaspores are common in savanna ecosystems, enabling distribution into isolated islands of savanna.

Most of the larger areas of savanna, such as those of Roraima, the savannas of the Rio Paru region of Pará state, and the extensive savannas around Santarém, also in Pará, occur within the drier and more seasonal regions of Amazonia. A belt of drier seasonal climate extends from Roraima to Santarém with under 2000 mm of rainfall and a strong dry season. Other savannas, especially some of the smaller patches, occur for edaphic reasons, such as an underlying hardpan.

There are a large number of savannas in Amazonian Venezuela and these were subdivided into three types by [Otto Huber \(1982\)](#): (1) grassy llanos and llanos-type savannas confined to the north of the region, (2) grassy inundated savannas of the Manapiare-Parucito basin, and (3) the true Amazonian savannas of the central and western part of Amazonas Territory. Unlike many of the Brazilian savannas, the Amazonian savannas of Venezuela have a high rate of endemism. They are mainly of edaphic, pre-Quaternary origin, whereas the llanos and inundated savannas are relict areas from the Pleistocene arid periods. The savannas of Amazonia are therefore not just one single ecosystem.

Other savannas also vary greatly in their botanical diversity and degree of endemism. The Roraima, Sipaliwini, and Humaitá savannas have few endemic species, whereas a few savannas have a rich and diverse flora. Most notable are those

of the Rio Cururu region of Pará, which occur over sandstone. The sandstone savannas of the Guayana region of Venezuela are also richer in endemism than those of central Amazonia. Savannas that occur over special edaphic conditions are generally much richer than savannas occurring in terrain with similar conditions to those of the surrounding forest. These edaphic savannas are probably older and more stable over time.

Along the northern fringes of Amazonia, other extensive savannas are the llanos of Colombia and the contiguous Gran Sabana of Venezuela. There are also extensive upland savannas in the Departments of San Martín and Madre de Dios in Peru. Overall, savanna covers approximately 15% of the Amazon region and so it adds considerable species diversity. Many of the savanna ecosystems are under threat by overuse for farming and agriculture. For example, much of the cerrado region is being destroyed to plant soy and the Roraima-Rupununi savannas are being intensively burned by cattle ranchers and more recently also for soy. In the dry El Niño years of 1998 and 2005, the fires spread into the rain forest, causing extensive destruction. [Nepstad et al. \(2004\)](#) showed that there is much reduced tree growth and how susceptible the terra firme forest is to fire in these years of drought.

Flooded Savannas of Eastern Amazonia

In the delta region of Amazonia in the state of Amapá and in the eastern half of Marajó Island, there are large areas of inundated savanna or campos de várzea as they are called locally. Other inundated savannas occur farther inland in Pará, especially between the Rios Xingu and Tapajós, and in the basin of the Rio Madeira in Amazonas, but these are much smaller than those of Marajó and Amapá. There are many species of grass in the flooded savannas, such as *Eragrostis hypnoides*, *Eragrostis glomerata*, *Parathera prostrata*, *Paspalum orbiculatum*, and *Phenakospermum guianense*. But the main difference between flooded and nonflooded savannas is the greater frequency of sedges (Cyperaceae) such as *Cy. giganteus* in the wettest areas and *Cyperus luzulae*, *Cyperus ferax*, and *Scleria geniculata* in the less flooded areas. Shrubs are less abundant in flooded savanna, but in areas that are grazed by cattle *Artemisia artemisiifolia* becomes so abundant that it can completely dominate an area because it is unpalatable to cattle. *Ipomoea fistulosa*, a shrub that is toxic to cattle, also increases on grazed land for the same reason. Other species characteristic of flooded savannas include *Aeschynomene sensitiva*, *Alternanthera philoxeroides*, *Capironia fistula*, *Cassia reticulata* (known locally as mata pasto or pasture killer because of its tendency to invade pasture), *Clitoria triquetrum*, *Justicia obtusifolia*, *Mimosa pigra*, *Montrichardia linifolia*, *Phaseolus lineatus*, *Rhabdadenia macrostoma*, *Sesbania exasperata*, and *Th. geniculata*.

In the flood season, various floating aquatic species, such as *Ceratopteris pteridioides*, *Eichhornia azurea*, *Nep. oleracea*, *Pistia stratiotes*, and *Salvinia radula*, multiply with great rapidity.

Montane Fringing Ecosystems

Around the northern and southern edges of Amazonia, on the older pre-Cambrian formations of the Guiana and Brazilian

crystalline shields, there are a number of hills and mountains, and to the west Amazonia is bordered by the Andes Mountains. These upland areas, which enclose the lowland Amazon basin on three sides, add considerably to the biological diversity of the Amazon ecosystem. Small changes in altitude or topography can cause significant changes in the vegetation type, physiognomy, species composition, and climate.

The Sandstone Tepuis of the Guayana Highland

An area with a complex mixture of vegetation types is the Guayana Highland, which is dominated by dramatic sandstone table mountains or tepuis. The mountain slopes are covered by lower and upper montane forest and often there is an abrupt change to open savanna and swamp formations on the summits of the mountains because of the sheer sandstone cliff faces. The highest mountains have less forest on their summits and more open vegetation except for gallery forest along the streams. The lower mountains have considerable areas of forest on their summits. For example, on Cerro Guaiquinima in Venezuela, one of the largest sandstone tepuis, 40% of the summit is covered by forest. Both tall forest and relatively low dense forest, as well as intermediate types, occur on Guaiquinima. There is a strong relationship in species content between the forest on the summit of this and other tepuis and the forest of the neighboring lowlands. Species endemism is high on the sandstone tops of the Guayana Highlands, and many genera have a series of closely related species with one occurring on each of the larger mountains, for example, the pitcher plant genus *Heliamphora* or the shrub *Tepuianthus*.

Two outlying tepuis, Tepequém and Araca, occur well within the Brazilian Amazon region, and Mounts Roraima and Neblina both lie on the Brazilian border with Venezuela (see Prance and Johnson, 1992). The latter is the highest tepui, reaching 3045 m in altitude. The Guayana Highland region is a complex mosaic of tepuis interspersed with rain forest or savanna depending on the locality.

Granite Inselbergs

Scattered throughout the Guianas and northern Amazonian Brazil are a series of granitic outcrops or domes that rise above the rain forest to a height of 300–800 m. In some cases these hills are covered by dense forest (e.g., Palunlouiméempeu and Mitraka), but most of them are characteristic inselbergs with low scrub forest and open areas of exposed rocks. These are obviously islands of a special type of vegetation surrounded by rain forest. The tops of the inselbergs are well drained and become very dry in the dry season, and so the vegetation is often dominated by sclerophyllous plants or species with other adaptations to drought, such as the orchid *Cyrtopodium andersonii* with large pseudobulbs that store water or various cacti (*Epiphyllum* and *Melocactus*). The dominant shrub is usually a species of *Clusia* and other terrestrial orchids include *Epidendrum nocturnum* and *Encyclia ionosma*, and the bromeliad *Pitcairnia geyskesii* is also common. Many of the plant species on the inselbergs of the Guianas are confined to that habitat. There has been considerable speciation in adaptation

to the summit of inselbergs with their arid dry season conditions and very humid rainy season conditions. However, in contrast to tepuis, there has been much less speciation between the different inselbergs, and local endemics are rare.

Low Hills within Amazonia

In addition to the tepuis and inselbergs scattered throughout the Amazon region are several lower hills that can have distinct vegetation. These are more frequent to the north of the Amazon River and near the Brazilian Shield region and are mostly outliers of the ancient shields.

Small changes in altitude can have extremely important effects on vegetation type, physiognomy, species composition, and climate. For example, outside Amazonia, small low hills in the arid northeast of Brazil tend to accumulate cloud and therefore are covered by tall moist forest called brejo. The brejo forests contain many Amazonian species. The different effects between larger and smaller mountains (known as the Massenerhebung effect), as well as latitude, on the vegetation type are quite striking in the Neotropics. Consequently, there are many small patches of montane or cloud forest on small outcrops throughout the lowland region. Also the altitudinal limits of the different forest types vary considerably depending on the effects of local climate, soil, and latitude. Some of the species and genera that occur on the higher mountains also occur on these areas, for example, *Retinophyllum* and *Pagamea* in the Rubiaceae.

The Andes Foothills

The Amazon region is bordered on the west by the Andes, which rise abruptly out of the lowland rain forest. Unlike the tepuis and inselbergs, the Andes are a relatively recently formed mountain chain and have a distinct zonation of the vegetation according to altitude. The forests of the eastern slopes fall into the ecosystems of Amazonia and add considerable variety of both vegetation types and species.

The lowland forest extends up the mountains to between 700 and 1000 m. Above that altitude it is replaced first by lower montane, and then by montane vegetation types. The montane forests can generally be divided into three zones: lower montane forest, upper montane forest, and subalpine forest.

Lower montane forest begins between 700 and 1200 m. It is quite similar to lowland rain forest, but a large number of species drop out and are replaced by more upland species. This forest tends to be lower in stature than that of the surrounding lowland area, and it has fewer woody vines and fewer buttressed trees. Vascular epiphytes are common and mesophyll leaf types are predominant. Many of the lowland taxa persist into this zone, such as species of *Licania* (Chrysobalanaceae) and *Eschweilera* (Lecythidaceae), but a number of distinctly highland elements also enter the lower montane forest, for example, in the Colombian Andes, *Brunellia comocladifolia*, *Alchornea bogotensis*, and *Cinchona calycina*. Palms such as *Euterpe purpurea* and *Wettinia cladospadyx* are quite abundant, and woody vines include *Anomospermum occidentale* and species of *Passiflora* and *Paullinia*. This zone typically

extends upward to between 1800 and 2400 m depending on latitude and local conditions.

The upper montane forest begins at 1800–2400 m and may extend in places up to 3400 m. It is usually of lower stature than the lower montane forest, with a predominance of microphyllous trees. Vascular epiphytes are still common and woody lianas are rarer. An increasing number of species characteristic of higher altitude enter the flora, for example, *Brunellia occidentalis*, *Weinmannia balbisiana*, *Symplocos pichindensis*, and the vines *Hydrangea peruviana* and *Liabum megacephalum*.

The subalpine forest, including the dwarf elfin forests, is of frequent occurrence in the Andes and extends locally into Central America. It is microphyllous or, at its altitudinal extreme, nanophyllous or dwarf-leaved. Few vascular epiphytes and climbers occur, but there are abundant bryophytes and lichens. This formation may extend up to 3800 m in some places, above which it is replaced by the herbaceous alpine formations such as páramo, puna and *Polylepis* forest which are not discussed here. The subalpine forest has few predominantly lowland genera but many that are characteristic of the highlands, for example, species of *Weinmannia* (Cunoniaceae) and *Gymoxys* (Asteraceae), *Brunellia* (Brunelliaceae), *Clusia* (Clusiaceae), *Befaria* (Ericaceae), *Miconia* (Melastomataceae), and *Rhamnus* (Rhamnaceae).

A most interesting type of dry forest occurs in small isolated dry valleys that are scattered along the Andes due to local weather conditions. They are significant as a link between the larger arid areas, and they were probably more nearly connected during the dry periods of the Pleistocene and early Holocene (see Pennington *et al.*, 2000). Important genera in these valleys include *Acacia*, *Bursera*, *Caesalpinia*, *Cercidium*, *Prosopis* (*Prosopis chilensis* and *Prosopis limensis*), and many Cactaceae. Linares-Palomino *et al.* (2003) conducted a multivariate analysis of the tropical dry forests some of which are on the fringes of Amazonia.

Campo Rupestre

The campos rupestres, or open formations on rocks, are generally confused with open savanna and the orchard savanna on terra firme, but they are quite different physiognomically and floristically. They develop on rocks and in rocky terrain, because they suffer drought in the dry season despite the equatorial humid climate, and because there is no possibility for water retention and all rainfall runs off immediately. Typical species of the cerrado do not occur here, such as *Cu. americana*, *Ha. speciosa*, *Salvertia convallariodora*, and *Q. grandiflora*. Instead there are various species of *Byrsonima*, *Clusia*, *Norantea*, and *Vellozia*, certain Bromeliaceae (*Bromelia*, *Dyckea*, and others), and many Eriocaulaceae (*Paepalanthus* and *Syngonanthus*). Lichens are also frequent and cover many of the rocks.

Campos rupestres are also quite common in central Brazil, where they are often confused with cerrados. For example, Serra do Cipó in Minas Gerais, much cited in the literature because of its interesting landscape and large number of Velloziaceae, is mostly composed of campo rupestre. In Amazonia, Serra do Cachimbo, in the southwest of Pará, has

an area of campo rupestre that covers about 16,000 km². Another large patch is the campo of the Rio Cururú, in the Tapajós River basin. At Ariramba, on the Rio Trombetas, both savanna and campo rupestre occur.

The canga or ironstone vegetation, which occurs on Serra dos Carajás over the iron deposit there, is also a special form of campo rupestre. On this formation, various extra-Amazonian species are common, such as *Pilocarpus microphyllus*, which occurs also in the northeastern states of Piauí and Maranhão; the extra-Amazonian genus *Callisthene* is represented by *C. microphyllus* of central Brazil, which occurs only within Amazonia on Serra dos Carajás. Also found on Carajás is the curious and beautiful treelet *Norantea goyasensis*. The branches of this thick-barked treelet sometimes lengthen and turn it into a vine. A review of vegetation on canga and the threats to it is given in Jacobi *et al.* (2007).

The Amazonian montane forests also show a strong affinity to campo rupestre and some could even be classified as floresta rupestre (i.e., forest on rock). In the mountain areas there has been a great accumulation of organic matter because, although the forests sometimes endure short dry periods, they are maintained by the high air humidity and mist.

Secondary Forest

Unfortunately, secondary forest is of increasing importance in Amazonia owing to the amount of felling of primary forest that is taking place. Obviously the species that now dominate secondary areas had a natural distribution prior to the occurrence of man-made secondary forest. A few secondary forest species are found throughout the tropics, and others grow in open spaces beside rivers, on old landslides, in gaps caused by tree falls or dead trees, or where forest has been felled by severe storms. Because the seeds and stumps have not been destroyed by fire, regenerated vegetation of naturally cleared areas is different from that in areas burned by man. Secondary forest species do not generally occur in the transition regions between forest and savanna. Modern vegetation maps show an increasingly large area of a new man-made vegetation and also of agricultural areas, but these are not discussed here. Some of the characteristic genera of secondary forests are *Cecropia*, *Byrsonima*, and *Vismia*. In Brazil, secondary forest is known by the term capoeira. More recently attention has been drawn to the importance of secondary forests for the biodiversity that they hold, for example, Chazdon *et al.* (2009). A comparison of the diversity of primary and secondary forests is given by Barlow *et al.* (2007) and they concluded the primary forest is of irreplaceable value. Almeida *et al.* (2010) provided an estimate of the area of secondary forest in Amazonian Brazil.

Conclusions

This summary of the principal vegetational formations that occur in Amazonia shows the considerable diversity that accounts for the approximately 30,000 species of vascular plants within the region. Many of the ecosystems described here could be subdivided further into other different local

communities. A knowledge of this ecosystem diversity and the distribution of species is an essential tool for the conservation and sustainable use of the region. To preserve the diversity of Amazonia, it is vital to conserve areas of each different type of vegetation because of the number of unique species of plants and animals that each ecosystem contains.

Antarctic Ecosystems

Peter Convey, British Antarctic Survey, Cambridge, UK

Published by Elsevier Inc.

Glossary

Ablation Direct transfer of water molecules from ice crystals to the vapor phase, without transition through the liquid phase.

Alien Nonindigenous species whose introduction and transient or established presence at an Antarctic location is known or considered most likely to be linked with human activity.

Anhydrobiosis Ability of certain organisms to lose virtually all water from their bodies under certain conditions, yet remain viable when subsequently rehydrated.

Cryoturbation Process by which soil particles and stones are moved and mixed by the frequent formation and subsequent melting of ice crystals in the soil column.

Cryptogam Plants without apparent reproductive organs; reproduction by spores.

Fellfield Dry, windswept habitat of cold regions comprising mineral soil, gravels, stones, and rock, dominated by cryptogams (especially mosses and lichens) and, outside the Antarctic continent, by compact cushion-forming phanerogams and short grasses.

Microclimate Climate experienced over a scale of mm to cm, within which the majority of Antarctic terrestrial biota (invertebrates, plants, and microbes) exist.

Microhabitat Small-scale habitat within which an organism or community exists.

Nunatak Isolated ice-free summit of a mountain whose bulk is permanently below the surface level of an ice sheet.

Phanerogam Plants with conspicuous reproductive organs (flowers); reproduction by seeds.

Phylogeography Studies concerned with the principles and processes governing the geographic distributions of genealogical lineages, especially within and among closely related species.

Propagule Any part of an organism capable of developing into a new individual (e.g., seed, spore, gemma, lichen soredium, egg, shoot fragment, etc.).

Sub-nivean Environment beneath a temporary, seasonal, or permanent covering of snow.

Synanthropic Referring to a species whose presence is intimately linked with human activity (i.e., only occurring in occupied buildings etc.).

Antarctica

Introduction to the Continent

Antarctica is distinct amongst the Earth's continents, not least because it is the only one not to have a long-term history of human occupation and influence. Antarctica is isolated from other continents by the 1000 km Drake Passage, and by 4000–5000 km from Australia and South Africa (Figure 1). More than 99.6% of its area is covered permanently by snow or ice, and ice-free ecosystems are limited to exposed nunataks, cliffs, and seasonally snow and ice-free areas. Terrestrial habitats are best represented in coastal regions, where most of the biodiversity is found, particularly along the Antarctic Peninsula, and in the major mountain ranges inland. Most ice-free areas are of small extent and isolated from others by distances of tens to hundreds of kilometers. However, in the McMurdo Dry Valleys of southern Victoria Land, exposed areas of several hundred square kilometers exist. Large areas of the continent are classified as cold deserts, with extremely low precipitation rates (much of which is then lost by ablation).

In contrast with the Arctic, which includes the northern fringes of continents surrounding a generally shallow ocean, Antarctica is an ice-bound continental mass surrounded and isolated by a large extent of cold ocean. This simple geographical difference is sufficient to create the large climatic differences found between the two polar regions at any specific latitude, and leads to a fundamental difference in colonization patterns. With continuous southward land connections,

recolonization of Arctic regions following post-Pleistocene deglaciation was relatively simple. In contrast, the extreme isolation of terrestrial and freshwater habitats across Antarctica from plausible refugia or other continental sources of colonists, combined with the obliteration of most but not all habitats during glaciation, have led to much lower colonization rates and levels of diversity for many faunal, floral, and microbial groups.

Tectonic, Glacial, and Biological History

Antarctica was an integral element of Gondwana. As these elements separated, its last continental links were with Australia and South America. The connection with South America, via what was to become the Antarctic Peninsula, was lost approximately 30–35 million years ago (Livermore *et al.*, 2005). At this time, fossil evidence indicates that Antarctica possessed a cool temperate fauna and flora. The separation of Antarctica and South America allowed development of circumpolar ocean currents, eventually isolating Antarctica from lower latitude sources of heat energy, and accelerating the continent's gradual cooling and formation of continental-scale ice sheets. The extent of glaciation has varied widely both geographically and over time during the last *c.* 40 my (Tripati *et al.*, 2005). Tundra-like ecosystems persisted in Antarctica through this period until at least 12–13 Ma (Lewis *et al.*, 2008) and possibly more recently (see discussion in Convey *et al.*, 2008).

Figure 1 Antarctica's geographical relationship with the other Southern continents, and the three commonly described terrestrial biogeographic zones within the Antarctic region.

Pleistocene glaciation mirrored that of the Northern Hemisphere, with the continent spending the majority of time over at least the last 800,000 years in the glacial phase of glacial–interglacial cycles (EPICA, 2004). At maximum, the continental icecap was considerably deeper than now, and the continent was surrounded by extensive ice shelves. The island groups of the South Shetlands, South Orkneys, and South Georgia are similarly thought to have been the centers of large ice caps, with current glaciological models suggesting that terrestrial habitats would have been limited to isolated and higher altitude inland nunataks. However, there is increasing recognition that reconciling the next generation of finer resolution glaciological models with biogeographical and phylogeographical evidence supporting ancient and relictual distributions is a pressing challenge (Convey and Stevens, 2007; Convey *et al.*, 2008, 2009; Vyverman *et al.*, 2010).

Antarctic Terrestrial Biogeographic Zones

Most authors have long recognized three biogeographic zones: the sub-, maritime, and continental (or frigid) Antarctic

(Figure 1), whose ecosystems are distinctively different. This formulation is retained in the descriptions below, for ease of comparison with the existing literature. However, recent plant biogeographic analyses (Peat *et al.*, 2007) refined the boundaries and components of the maritime Antarctic, whereas Chown and Convey (2007) highlighted the biogeographic strength of the division between the southern Antarctic Peninsula and the remainder of the continent, defining the “Gressitt Line,” which is analogous to the Wallace Line of southeast Asia.

Sub-Antarctic

The core sub-Antarctic islands include a ring of isolated Southern Ocean islands and Archipelagos. Except South Georgia, Heard, and McDonald Islands, the majority of these (Marion and Macquarie Islands, and the Crozet and Kerguelen archipelagos) lie either close to or north of the Polar Frontal Zone, a circumpolar oceanic feature where cold Antarctic surface waters sink below warmer sub-Antarctic waters (Selkirk, 2007). Some authors include further groups (Falkland

Table 1 Typical air and microhabitat temperature ranges experienced in summer and winter in each of the Antarctic biogeographical zones

Antarctic zone	Months with positive mean air temperatures	Air temperature range (°C)		Microhabitat temperature range (°C) (exposed habitat minima in parentheses)	
		Summer	Winter	Summer	Winter
Sub-Maritime	6–12	–2–+25	–10–+15	–5–+30	> –2–(–10)
Continental coastal	1–4	–10–+15	–45–+5	–5–+30	–20–+3 (–45)
Inland (deserts and nunataks)	0–1	–20–+10	–40––5	< –10–+30	(–40)
	0	–31–+9	–48––12	–29–+17	–47––16 (< –60)

Note that few data are available from microhabitats in the continental Antarctic, particularly during winter; considerably more negative minima would be expected in sites without snow cover.

Islands, Gough Island, Îles Amsterdam and St Paul, New Zealand's outlying groups of Snares, Campbell, Bounty, and Chatham) either within the sub-Antarctic or in a separate "mild Antarctic" classification. More correctly these are southern cool temperate or ocean temperate, containing faunal and floral groups not otherwise represented in the sub-Antarctic. Sub-Antarctic island climates are strongly oceanic and, with the occasional exception of South Georgia, they are not influenced by seasonal pack or fast ice. Mean air temperatures of most islands are low but positive year-round, and precipitation is high (Table 1). With the exception of South Georgia and Heard Island, most islands are now or have been only partially glaciated.

Maritime Antarctic

The maritime Antarctic also experiences a considerable but more seasonal oceanic influence on climate. The zone includes the western coastal regions of the Antarctic Peninsula to Alexander Island (ca. 72° S), along with the Scotia arc island archipelagos (South Shetland, South Orkney, and South Sandwich Islands), and the isolated Bouvetøya and Peter I Øya. Mean air temperatures are marginally positive for 1–4 months of the year; however, both summer maxima and winter minima (Table 1) are buffered by the surrounding ocean, the surface temperature of which varies annually between ca. –2 °C and +1 °C. Short thaws are possible in all winter months. Precipitation is generally high but varies with location and time. The South Sandwich archipelago and Bouvetøya are unusual in being geologically recent (1–3 my old) and active volcanic islands, with unique biological communities associated with geothermal activity (Convey *et al.*, 2000; Convey and Smith, 2006). Together with analogous areas on Deception Island (South Shetland Islands) (Smith, 2005) and in Victoria Land (continental Antarctic) (Skotnicki *et al.*, 2001), these are exceptional in Antarctica.

Continental Antarctic

This zone conventionally comprises most of the continental area of Antarctica, including all of East (or Greater) Antarctica, the Balleny Islands, and the eastern side of the Antarctic Peninsula. However the inclusion of the latter element, other than on climatic grounds, is put into doubt by recent analyses (Peat *et al.*, 2007; Chown and Convey, 2007). With the exception of the Dry Valley region of Victoria Land, terrestrial habitats are of limited extent and great isolation. In addition

to the cold deserts, they include exposed coastal regions similar to those of the maritime Antarctic and inland nunataks. Positive mean air temperatures are achieved for <1 month in coastal locations and never inland (Table 1). Air temperatures rarely if ever become positive even for short periods in summer. As elsewhere, microhabitat temperatures do not track air temperatures closely, due to warming from solar radiation in summer, and protection from winter extremes by snow cover. Beyond the Antarctic Circle, habitats inevitably experience winter darkness with no thermal input, during which those that are unprotected (e.g., exposed mountain ridges, cold deserts) are expected to track air temperature patterns and minima closely.

Antarctic Terrestrial Biota

Habitats

In the maritime and continental zones, with the exceptions of steep cliffs and exposed mountain ridges, most terrestrial habitats are covered seasonally by snow or ice, protecting from extreme temperature variation and wind abrasion. Although habitats in the maritime and continental zones may be free of seasonal snow cover, if at all, for periods of only days or weeks up to c. 5 months, many sub-Antarctic islands experience only intermittent snow cover, often restricted to higher altitudes. Even on the coldest islands sub-nivean microhabitat temperatures are often sufficient to allow year-round biological activity. This is not the case in the maritime and continental zones, where biological processes are arrested by low winter temperatures.

Antarctic soils are typically poorly developed, with low organic content (Beyer and Böler, 2002). Formation, development, and stability of soils are heavily influenced by cryoturbation. There is a clear dichotomy between those of the sub-Antarctic and the other two zones, with only the latter possessing a widespread permafrost layer. Brown soils are associated only with the larger stands of higher plants (phanerogams) in the maritime Antarctic, are not present in the continental zone, but are more widespread in the sub-Antarctic. Deep peat deposits have developed under extensive valley bog communities in the sub-Antarctic, and are radiocarbon dated as forming soon after the end of the Pleistocene glaciation (10–20,000 years b.p.). Peat deposits are much

Table 2 Dominant biotic components of typical ecosystems of each of the Antarctic biogeographical zones

Zone	Flora	Fauna	Microbiota
Sub	Phanerogams, cryptogams; open fellfield (<i>cf.</i> maritime zone) at higher altitude; alien species	Arthropods (esp. Diptera, Coleoptera); microarthropods (Acari, Collembola); micro-invertebrates (Nematoda, Tardigrada, Rotifera); alien vertebrates and invertebrates	Various groups
Maritime	Closed and open cryptogamic communities; phanerogams very limited	Micro-arthropods; micro-invertebrates; Diptera very limited	algal and cyanobacterial mats; foliose algae; protozoa
Continental	Cryptogams, very limited extent	Micro-invertebrates; micro-arthropods more limited	Algal and cyanobacterial mats; protozoa; endolithic microbiota

more restricted in the maritime zone (maximum age 5–6000 years b.p.) and not found in the continental Antarctic.

Terrestrial Fauna

Native terrestrial vertebrates, limited to a single endemic insectivorous passerine and freshwater ducks on South Georgia and Kerguelen, and two scavenging sheathbills, form a very small element of the fauna of Antarctica. There are many records of vagrant birds, particularly from sub-Antarctic islands, the majority of which succumb to the extreme conditions or predators. There are no native mammals, reptiles or amphibians. Terrestrial habitats are influenced (guano deposition, aerosol dispersal, trampling) by the abundant Antarctic marine vertebrates (penguins, seabirds, seals), which come ashore to breed, rest or molt. Most impacts are coastal, but birds such as Antarctic and snow petrels and south polar skuas also breed on nunataks several hundred km inland.

The terrestrial faunas of each Antarctic zone, therefore, consist of invertebrates (Table 2). The sub-Antarctic islands include “higher” insects and other arthropods, although many familiar groups are not present (e.g., Odonata, Trichoptera) or are represented by very few species (e.g., Araneae, Isopoda, Lepidoptera, Hymenoptera and Hemiptera). The most diverse insect groups are Diptera and Coleoptera. Molluscs and annelid worms are also present along with communities of microarthropods (Acari, Collembola) and microinvertebrates (Nematoda, Tardigrada and Rotifera). These have received less critical attention than the larger and more obvious groups, as is also the case with the (polyphyletic) Protozoa.

Maritime Antarctic faunas include fewer higher taxa, with only two chironomid midges (Diptera) present. The most studied faunal elements are a minority of the species of Acari and Collembola, although microinvertebrates are also well represented. Species diversity in all groups is low, but population densities are often high, in the range 10^4 – 10^7 individuals m^{-2} , comparable with or greater than many temperate ecosystems. Food webs have a simple structure, with very low representation of predators. Microinvertebrates include genera with characteristic trophic preferences (e.g., algivory, bacterivory, fungivory, and nematophagy); however, little detailed autecological work has been attempted and the diets of Antarctic taxa are virtually unknown (Hogg *et al.*, 2006).

The fauna of the continental Antarctic gives a further simplification, including no insects, and with microarthropods only reaching levels seen in the maritime zone in the much more limited areas of vegetation and nutrient enrichment. This zone includes the simplest faunal ecosystems on the planet, where even nematodes are absent (Convey and McInnes, 2005).

Terrestrial Flora

Large-scale patterns in the Antarctic flora mirror those of the fauna (Table 2). Smith (in Laws, 1984) provides the most authoritative ecological description and comparative treatment of Antarctic floras, which remains valid despite many advances in detailed taxonomic knowledge. Monographs are available of the Antarctic lichen (Øvstedal and Smith, 2001) and bryophyte (Ochyra *et al.*, 2008) floras.

The flora of the sub-Antarctic is the richest and most diverse, and shows affinities with either South America (Fuegia) or Australasia (New Zealand). Trees and shrubs are absent (excepting the dwarf shrub *Coprosina* on Macquarie Island). Sub-Antarctic vegetation is superficially similar to, and climate, land form and pedology comparable with those of Arctic tundra, but the two regions differ in several important respects. Sub-Antarctic soils do not contain a permafrost layer, whereas the only woody plants are dwarf-shrub-like rhizomatous herbs (*Acaena*). The vegetation includes exceptional development of large rosette-forming “megaherbs” and tall grasses, encouraged by the lack of native grazers. Phanerogams are best developed in low altitude coastal regions. With increasing altitude, they are replaced by a cryptogamic fellfield flora, closely similar to that of the maritime Antarctic.

The most favorable habitats of the maritime Antarctic are dominated by cryptogamic communities of carpet- and turf-forming mosses. Extensive vegetated areas are limited to a narrow altitudinal range (to c. 150 m.a.s.l.) in coastal regions. Inland, at higher altitudes, and at more exposed coastal sites, open fellfield communities occur, including cushion and turf-forming mosses, liverworts and crustose, foliose, and fruticose lichens. Phanerogams are represented by the hairgrass, *Deschampsia antarctica*, and pearlwort, *Colobanthus quitensis*, which also occur in the sub-Antarctic and the South American Andes.

Cryptogamic vegetation is fragile and, lacking roots, sensitive to physical disturbance, for example in the vicinity of penguin and seal colonies. Such areas tend to be dominated by the foliose alga, *Prasiola crispa*. One consequence of the rapid recovery of Antarctic fur seal (*Arctocephalus gazella*) populations, following near extinction through hunting, has been the occupation of new summer resting and molting sites within terrestrial habitats of the sub and maritime Antarctic. The plant communities of these areas are unable to withstand excessive seal trampling and nutrient enrichment and have largely been destroyed.

Continental Antarctic vegetation is categorized within the same system as that of the maritime zone, although lichen sub-formations predominate. No phanerogams are present, the extent of closed cryptogamic communities is much more limited and peat formations are absent.

Microbial Systems

Microbial autotrophs form the basis of polar terrestrial ecosystem processes (Vincent, 1988; Friedmann, 1993; Wynn-Williams, 1996), playing pivotal roles in the processes of primary colonization and stabilization of mineral soils, which allow secondary colonization and succession by other microbiota, plants and Metazoa. Autotrophic cyanobacteria and algae are the primary colonists, followed secondarily by bacteria, fungi, and protozoans (whose significant Antarctic members are heterotrophic flagellates, gymnamoebae, testate amoebae and ciliates).

In addition to the largely edaphic (on or within soils), epiphytic (on surfaces of living plants and lichens) and epilithic/hypolithic (on exposed or undersurfaces of rocks) habitats typically also occupied by faunal and floral communities, microbial ecosystems may also utilize cryophilic (between ice crystals) and endolithic (within surface few mm of rock matrix) habitats. The latter habitat is further divided into chasmoendolithic (within fissures and cracks open to the rock surface) and cryptoendolithic (within tiny cavities of the rock matrix). These cryptic habitats represent one limit to life on Earth and have been proposed as models assisting development of exobiological techniques (Wynn-Williams, 1996).

Microbial ecosystems have received most attention in more extreme terrestrial habitats, although the same groups are present and important in all three Antarctic zones. Groups such as algae and cyanobacteria form filaments and mats within water bodies and on/in the surface layers of damp soils. They are well represented within the maritime zone, and are often a climax community of the continental zone (Table 2). In large parts of the continental Antarctic Dry Valleys no detectable life survives on the surface of soils or rock.

Freshwater Systems

Freshwater ecosystems of the Antarctic possess a very simple structure when compared with those of the Arctic and lower latitudes. Perhaps most striking is the absence of fish. Their faunas include a single predatory diving beetle (only South Georgia), several Crustacea (cladocerans, copepods, ostracods, and anostracans), adventitious micro arthropods, nematodes,

tardigrades, rotifers, and protozoans. Ecosystem structure in the maritime Antarctic is even more simplified, the plankton containing single copepod (*Boeckella poppei*) and anostracan (*Branchinecta gaini*) herbivores, and the predatory copepod *Parabroteas sarsi* in addition to benthic cladocerans and ostracods and the microscopic groups. *B. poppei* provides an intriguing link between the maritime and continental Antarctic, which otherwise do not share any crustacean species.

The trophic impact of metazoans in lakes of all three zones is thought to be minimal, although data are lacking and there is disagreement over their importance in the sub-Antarctic lakes of South Georgia. With this exception, top-down grazing control is reduced, and the “microbial loop” - a microbial food web consisting of phytoplankton, bacteria and protozoans - assumes importance (Laybourn-Parry, in Lyons *et al.*, 1997).

Lakes in the maritime and continental zones are seasonally or permanently covered by ice. Some continental lakes are meromictic or hypersaline. Some are thought to be at least hundreds of thousands of years old. Lake Vostok, a 200 km long, 500 m deep lake beneath at least 3 km thickness of the continental icecap, is the largest of many subglacial lakes across Antarctica, with the possibility of harboring micro-organisms effectively isolated since the formation of a permanent ice barrier.

Present Day Biodiversity

Within Antarctica

Attempts to catalog and compare biodiversity of the three Antarctic biogeographical zones continue to be hindered by two fundamental problems - a lack of adequate or comparable sampling coverage, and taxonomic uncertainty (particularly the likelihood of extensive synonymy), both of which apply in varying extent to all the groups encountered (Chown and Convey, 2007). Currently, sufficient data do not exist to allow rigorous comparisons for any microbial groups. Worldwide as well as in the Antarctic, a tiny proportion of prokaryotes have been identified, with virtually no mention of species distribution. However, increasingly, the application of molecular biological techniques is indicating both a higher than previously realised level of microbial diversity in Antarctica (Cowan *et al.*, 2002), and that much of this diversity shows large levels of divergence (implying long-term isolation) from sequences available in current molecular databases (De Wever *et al.*, 2009; Vyverman *et al.*, 2010). This suggests that the “global ubiquity hypothesis,” which predicts that microbial groups do not face the same obstacles in dispersal as larger organisms, does not apply to Antarctic systems to the same extent as it does elsewhere.

The biodiversity of groups for which there are reasonable data in each of the Antarctic zones is summarized in Table 3 and Table 4. These data illustrate a large-scale trend of decreasing diversity with increasing environmental extremes from the sub to the continental Antarctic. However, although there have been several proposals of similar trends occurring within zones (particularly along the Antarctic Peninsula and in Victoria Land), the true picture appears to be much more

Table 3 Biodiversity of plant taxa in the three Antarctic biogeographical zones

Zone	Flowering plants	Ferns and club-mosses	Mosses	Liverworts	Lichens	Macro-fungi
sub-Antarctic	60	16	250	85	250	70
maritime Antarctic	2	0	100	25	250	30
continental Antarctic	0	0	25	1	150	0

Note that figures presented are approximate, as it is likely that (i) new species records will be obtained through more directed sampling, (ii) a significant number of unrecognized synonyms are likely to exist and (iii) taxonomic knowledge of some Antarctic groups is incomplete. The Scientific Committee on Antarctic Research, through its biological program 'Evolution and Biodiversity in Antarctica', maintains up-to-date and open access databases of known biodiversity in most terrestrial faunal and floral groups (see www.eba.aq).

complex (Adams *et al.*, 2006; Maslen and Convey, 2006; Peat *et al.*, 2007), in part related to the presence of suitable microhabitats, and in part to glacial history and the hypothesized existence of refuge sites and biodiversity hotspots.

Origin and Antiquity of Biota

The biota of Antarctica is most closely related to that of other southern continents. There are also examples of plant and microbial groups, with known ability to disperse *via* aerial propagules, with bipolar or alpine distributions (Longton, 1988; Broady, in Wynn-Williams, 1996; Øvstedal and Smith, 2001; Pearce *et al.*, 2009). Gross similarities between soil faunal communities of both polar regions (the dominance of Acari, Collembola and other microinvertebrates) indicate the generalist function of these groups in soil ecosystems worldwide.

Except in the sub-Antarctic, where some islands experienced incomplete glaciation, many coastal terrestrial habitats are likely to have been obliterated during glaciation. As a large proportion of extant biota in all three zones is found in low-lying coastal areas, it is unlikely that they survived glacial maxima in higher altitude nunatak sites where, even now, they are not represented. However, at least among the Acari, Collembola, Tardigrada, Nematoda, and the lichens, many species and some genera are endemic to one or more of the Antarctic zones, supporting a prolonged regional presence (Øvstedal and Smith, 2001; Pugh and Convey, 2008). The wide distributions of some representatives of these groups within zones must be as a result of postglacial expansion from as yet unidentified refugia. In contrast, mosses show much lower levels of endemism (Ochyra *et al.*, 2008), suggesting that the contemporary flora may have developed mainly through postglacial recolonization. The use of molecular biological approaches to estimate divergence dates clearly identifies examples of regional presence over millions of years in the continental, maritime and sub-Antarctic (Stevens *et al.*, 2006; Mortimer *et al.*, 2010), as well as separation events estimated to have taken place at least 30–40 Ma (Allegretti *et al.*, 2006), some of which may be linked to the geological split of the Antarctic Peninsula from South America (see Convey and Stevens, 2007; Convey *et al.*, 2008, 2009a; Vyverman *et al.*, 2010).

Natural Colonization Processes

Contemporary Colonization

Although there are clear oceanic and atmospheric features that form barriers isolating Antarctica from lower southern

latitudes, over long timescales these barriers are porous to the movement of biota (Barnes *et al.*, 2006). Aerobiological sampling demonstrates the presence of viable colonizing propagules in the airspora, both from "local" (Antarctic) and distant sources (Pearce *et al.*, 2009), although propagule densities are several orders of magnitude lower than obtained in comparable temperate and tropical studies. Most records refer to microbial or lower plant groups (bacteria, cyanobacteria, fungi, algae, and bryophytes) and lichens. Direct evidence of colonization, on both short and long distance scales, is given by records of new populations on previously barren ground, and of previously unrecorded species in known sites. Compelling evidence is provided by the

colonization of heated ground at the few, very isolated, volcanically active sites spread around Antarctica. These sites are recent, short-lived and of limited area. Their bryophyte and arthropod (and, presumably, microbial) communities contain species not found elsewhere in the Antarctic, but with wider distributions in the sub-Antarctic, South America, or New Zealand (Convey *et al.*, 2000). Other than these exceptional instances, confirmation of natural faunal colonization events is problematical, as many Antarctic distributional records stem from specific studies at single locations by individual taxonomic experts.

Mechanisms

Natural colonization mechanisms may be classified into (i) directed active movement, (ii) assisted transport by other species or debris and (iii) passive transport by air or water currents (Hughes *et al.*, in Bergstrom *et al.*, 2006). No Antarctic terrestrial biota show migratory behavior and option (i) is discounted in explaining current patterns of Antarctic terrestrial biodiversity. However, several vertebrate and invertebrate species with well-known active dispersal characteristics are recorded as vagrants at sub and even maritime Antarctic locations, and some have become established on sub-Antarctic islands in recent years (Frenot *et al.*, 2005).

Assisted transport of nonparasitic invertebrates, plant seeds, and other propagules by vertebrates (birds), other invertebrates, and debris (e.g. driftwood) has been proposed as an important mechanism of Antarctic colonization by several authors (reviewed by Barnes *et al.*, 2006). Transport of terrestrial biota is most likely to be rapid, and *via* vectors that spend time associated with land masses during the austral winter, such as skuas, gulls, and sheathbills (thus coming into contact with terrestrial biota) rather than marine mammals and birds that spend the winter period wholly at sea.

Passive transport in either air or water currents is also plausible, but there is little explicit evidence of its occurrence. Some arthropods, such as oribatid mites and springtails, show rafting behavior or high tolerance of submersion in seawater, as well as including many littoral or marine representatives. Others show no such ability. Transport in the air column presents the twin challenges of low temperature and desiccation. Although many Antarctic biota possess well developed resistance adaptations to these stresses, such transport is most likely to be survived by organisms with specific dispersal (lichen soredia, moss spores) or resistant stages (tardigrade "tuns," anhydrobiotic nematodes, rotifers, protozoan cysts). However, no attempt has yet been made to model or experimentally determine potential or actual survival of such processes.

Dispersing Propagules

Investment in dispersal features is not a characteristic of the "adversity-selected" life histories typical of Antarctic plants and animals (Convey, 1996). Nevertheless, all Antarctic organisms require the ability to disperse over a range of scales, from the mm/cm required to move between areas of favorable microhabitat, through the m/km required for local

colonization of icefree ground within the Antarctic, to the hundreds or thousands of km necessary to allow intra or intercontinental dispersal. The wide distribution of most Antarctic species in suitable habitats, particularly within the maritime and continental zones, combined with the recent age of most of these islands of habitat, argues for their success in dispersal.

Various Antarctic microinvertebrates (protozoans, rotifers, tardigrades, and nematodes) can potentially disperse in a resistant desiccated (anhydrobiotic) state. Likewise, algal and cyanobacterial mats and mosses survive long periods of unfavorable conditions in a desiccated state and are subjected to fragmentation and wind dispersal. Lichens, bryophytes, and fungi possess sexually and asexually produced dispersing propagules.

Future Trends

Anthropogenic Influences

Both the Antarctic continent and Southern Ocean were immune from human impact until recent times. Since the early nineteenth century, marine ecosystems have been devastated, at first due to the uncontrolled exploitation of marine mammal (seal, whale) populations and, more recently, the continuing though more controlled impact of various fisheries either directly on their target species or on nontarget bycatch. Human impact on the terrestrial environment commenced with visits of sealing and whaling vessels to sub and maritime Antarctic islands (Convey and Lebouvier, 2009), followed by the first landings on the Antarctic Peninsula and continent approximately 100 years ago. Initiated by the International Geophysical Year (1957/58), many scientific research stations have been erected around the continent, importing personnel and materials into the biome. This has been followed since about 1970 by rapidly increasing tourist operations. Antarctic terrestrial ecosystems are fragile and sensitive to disturbance, often existing on the same areas of icefree ground where research stations are established, and also where large concentrations of wildlife attract tourists. Therefore, human presence has inevitably disturbed and, locally, destroyed areas of terrestrial habitat (Tin *et al.*, 2009). Even before the expansion of these direct impacts, the global consequences of human activity were detectable throughout Antarctica in the form of chemical pollutants (Bargagli, 2005).

Introduction of Alien Organisms

The most obvious direct biological impact of human activities is in the introduction of alien organisms. Accidental introductions and deliberate transplant experiments have shown that a wide range of flora, fauna, and microbes are capable of surviving and establishing viable populations, whereas an even greater number have been recorded on a transient or synanthropic basis (Frenot *et al.*, 2005; Greenslade, 2006; Table 5). The greatest impacts have been on sub-Antarctic ecosystems, with the longest record of human influence and least extreme climate. Here, various vertebrates have been introduced both accidentally (rats, mice) and deliberately (fish, chickens, rabbits, cats, pigs, sheep, moufflon, cattle, and

Table 5 The occurrence of alien non-indigenous species across Antarctic biogeographical zones

reindeer) to most major islands (Convey and Lebouvier, 2009). In some cases, the consequences of these introductions are irreversible, whereas in others effective control measures appear to be impracticable. The ecological impact of some introductions (e.g., cats, grazing mammals) has been drastic but, generally, appropriate studies have not been made. Introduced species may have both direct (e.g., predation of bird eggs and terrestrial invertebrates, trampling and grazing of plants) and indirect impacts (e.g., alteration of habitat structure leading to changes in species dominance or behavior) on native species.

Introductions of invertebrates are less well documented at most locations. All alien invertebrates (with the exception of rabbit fleas used to disperse the myxoma virus amongst some introduced rabbit populations) have been introduced accidentally, with stores, food, equipment, domestic animals, etc, associated with human settlement (Frenot *et al.*, 2005). Although many have persisted only as long as human occupation continued, some have become established (particularly in the sub-, but also in the maritime Antarctic), with evidence of competitive displacement and local extinction of native species, and of new trophic links being introduced to terrestrial ecosystems.

Introductions of flowering plants, bryophytes, and microbes have also accompanied human occupation. Again, the sub-Antarctic has been most affected (Table 5), although many Arctic, sub-Antarctic, and some temperate vascular plants are also capable of long-term survival of maritime Antarctic conditions. Data on microbial introductions are sparse, although the process is inevitable via human transport (see Broady, in Wynn-Williams, 1996) and complete control measures impracticable. Given the possible evolutionary isolation of Antarctic microbes, the potential for damage to this unique biological resource should not be underestimated.

Regional and Global Environmental Change

Description and understanding of global climate change currently receives much attention from scientists, politicians, media and the general public. Most global climate models agree in predicting that any regional temperature increases will be greatest and most rapid at high latitudes. There is clear evidence of rapid regional warming trends at several maritime and sub-Antarctic research stations, along with changes in other environmental variables affecting various parts of the

continent (Turner *et al.*, 2009; Convey *et al.*, 2009b). Warming rates along the Antarctic Peninsula are among the most rapid seen worldwide.

Another important prediction of climate change models is of changing patterns of precipitation, altering water input to terrestrial habitats. Spatially detailed predictions are not yet available for Antarctica, although the role of water as possibly the single most important factor limiting distribution of Antarctic terrestrial biota is well recognized. At a local scale, water availability to terrestrial ecosystems can undergo drastic change as a result of factors as simple as the complete exhaustion of a snow bank or, conversely, increased release of water from melting icefields. These effects may be caused by changes in either the timing or amount of snow accumulation, or the duration of positive summer temperatures (i.e., in combination with temperature amelioration).

A separate anthropogenic influence on Antarctic and high latitude Southern Hemisphere ecosystems – the ozone hole – has existed since the early 1980s. Its formation leads to a temporary but drastic reduction in stratospheric ozone concentration, allowing a disproportionate increase in the exposure of terrestrial (and shallow marine) ecosystems to potentially damaging shorter wavelength UV-B radiation. Levels experienced at any site vary depending on the pattern of movement of the ozone hole, and modulation by factors such as clouds and snow cover but, at worst, exposure levels (integrated over time) comparable to those of the tropics are experienced.

Biological Consequences of Climate Change

Prediction and identification of the effects of climate change processes in the Antarctic terrestrial environment has received critical attention over the last decade (see Kennedy, 1995; Convey, 2003; Bergstrom *et al.*, 2006 for review). Many indigenous Antarctic terrestrial biota exhibit sufficient ecophysiological flexibility to absorb and even benefit from both the direct and indirect (e.g., changed nutrient availability) effects of predicted levels of change. However, how individual species responses may be integrated to community or ecosystem level is unknown in Antarctic systems, although recognized as a key research challenge (Day, 2001; Convey, 2003). Any amelioration is likely to influence Antarctic ecosystems and biodiversity

further by easing the constraints that limit colonization and establishment of alien species (Frenot *et al.*, 2005).

The effects of warming are expected to be greater at high latitude sites that already have a very restricted thermal energy budget, where the relative importance of a small temperature increment will be of greater significance. Thus the main consequences of temperature amelioration (assuming continued water availability) are to increase the effective length of season and thermal energy budget, in turn leading to increased growth, reproductive rates, and population sizes both of photosynthetic autotrophs and heterotrophic microbial and invertebrate species. The evidence available from observational and manipulation studies in the Antarctic supports this contention (Convey, 2010). As also reported from the Arctic, there is considerable variability in the responses seen, with some biota responding very rapidly or significantly, whereas others, or their habitats, appear to be robust or buffered to change (Hodkinson *et al.*, 1998).

Some climate change processes are likely to be deleterious for Antarctic biota, at least at a local scale. Any decrease or total loss of water input to ecosystems could lead to local extinctions and drastic changes in ecosystem structure. Likewise, should maximum exposure to ozone hole related UV-B radiation surpass the tolerances of exposed biota, particularly colonizing microbiota with crucial roles in soil stabilization and permitting secondary colonization by other organisms, some terrestrial habitats may become barren. Such drastic eventualities are yet to be reported from the Antarctic. Much more likely and ecologically relevant, but harder to quantify, are changes in patterns of organism investment in the eco-physiological and biochemical responses (e.g., cryoprotectant, UV screening pigment production, and repair processes) required to permit survival of changing patterns and intensities of environmental stress (see Snell *et al.*, 2009 for an example relating to UV screening pigments in plants).

Climate amelioration will lead both to an increased area of available terrestrial habitat and a longer “window of opportunity” within which to complete the dual processes of colonization and establishment. With or without human assistance, this will lead to increases in biodiversity and changed community composition, and, in turn, to greater trophic complexity and the inclusion of higher trophic levels. The resistance of indigenous Antarctic biota to these processes is unknown, although they are generally thought to be poor competitors.

Acknowledgments

I thank the British Antarctic Survey (BAS) for resources and the many BAS colleagues, and members of the international SCAR biological community, who have been involved in many discussions over time that have contributed to the development of the ideas in this paper.

Glossary

Arctic Geographically, the region lying to the north of latitude 66.7° N, but environmentally and in the context of this article, the region to the north of the climatically controlled northern latitudinal treeline that corresponds approximately to the mean July isotherm of 10 °C.

Permafrost The phenomenon of ground materials (e.g., soil and bedrock) that are at or below 0 °C for 2 or more years. Usually, but not always, any water present is in the solid state. The Arctic is characterized by the presence of large, continuous areas of permafrost that have the form of lower soil layers permanently frozen with a shallow (usually < 1 m) ‘active layer’ that freezes and thaws each year and accommodates belowground biological activity.

Refugia In the context of the Arctic, these are land areas that were not covered by ice sheets or glaciers during the last glaciation. Consequently, some biota could survive there and recolonize adjacent areas when the ice retreated. Therefore, these areas are associated with high biodiversity and endemism. Refugia usually occurred in coastal areas (now continental shelves) and ice-free mountain tops or “nunataks.”

Sub-Arctic The ecotone (ecological boundary zone) connecting the treeless tundras in the north with the taiga or coniferous boreal forests in the south. The area is characterized by the presence of scattered, deciduous or coniferous trees of low stature and is sometimes termed “forest tundra.” (Other Arctic vegetation zones are described in the text.)

Treeline Here, denotes the northern latitudinal and altitudinal distribution limit of vegetation in which trees are a conspicuous but not necessarily a dominant element. Individual, isolated trees or ‘oases’ of trees in environmentally benign areas are considered to be beyond the treeline.

Tundra This is a type of vegetation characteristically occupying the Arctic. However, the term is used in many ways, from characterizing individual plant communities of the Arctic, which consist of dwarf shrubs and sedges, to characterizing all vegetation above the altitudinal treeline and between the latitudinal treelines and the poles in both hemispheres. In this article, the term is used in the Russian sense to characterize Arctic vegetation lying between the taiga and the region of the polar deserts.

Introduction

Although Arctic environments have undergone dramatic changes over millions of years, the twentieth century was associated with particularly rapid changes in many aspects of the physical environment and particularly with rapid cultural and sociological changes in the north, leading to the increasing exploitation and fragmentation of wilderness areas. Because future environmental changes were predicted to be even greater during this century (ACIA, 2005; IPCC, 2007), it became increasingly necessary to document, monitor, and understand the biological resources of the Arctic. Understanding the patterns, causes, and consequences of biodiversity throughout the Arctic’s lands, as highlighted by Chapin and Körner (1995), is an important aspect of this challenge. However, the Arctic should not be seen as a region remote from the more populated regions of the world

at lower latitudes: Several hundreds of millions of birds overwintering in temperate regions migrate to summer nesting grounds in the Arctic, and the functions of many Arctic ecosystems in sequestering the greenhouse gas carbon dioxide in soils have contributed to cooling the earth’s surface since at least the end of the last ice age.

This article introduces the reader to current patterns of biodiversity in terrestrial Arctic ecosystems and presents further details of the physical, historical, and biotic environments that have shaped these patterns. The authors then show the importance of the Arctic’s biodiversity in terms of ecosystem function and its provision of resources for human life support and welfare (Chapin *et al.*, 2005). Finally, they show how the Arctic’s biota is threatened by numerous factors and discuss the major challenges to further understanding the biota.

Definitions and General Environmental Characteristics of the Arctic

The Arctic is difficult to define, basically because of two confounding issues – the earth's inclination to the sun and environmental, including climatic, conditions (Nuttall and Callaghan, 2000). Strictly, the Arctic is the area north of latitude 66.7° N, where the sun does not set below the horizon at midnight on midsummer's night and does not rise above the horizon at midday on midwinter's day. This astronomical feature sets a definitive photoperiod for the Arctic and reduces the amount of solar heat absorbed by the earth's surface. Hence, the Arctic is characterized by having long, cold, and dark winters and short, cool summers with the midnight sun visible.

The energy balance of the earth's surface in the north is complicated, however, by the connectivity of the Arctic's oceans and climate with those further south. The transport of heat from southern latitudes into the Arctic in warm ocean currents creates environments which are much warmer than those that can be considered as typically Arctic, for example, those in northern Fennoscandia (Figure 1), which are warmed by the Gulf Stream. In contrast, where returning cold water flows southward, unusually cold climates exist for particular latitudes: Tundra environments exist in eastern Canada (Figure 1) at latitudes at which British agriculture and forestry thrive. Proximity to the coast affects terrestrial temperatures by the formation of mists and increasingly by loss of sea ice (Bhatt *et al.*, 2010). On land, topography also affects temperatures locally, particularly in summer, whereas proximity to large lakes affects temperatures in winter (Zhenlin *et al.*, 2011). As one moves closer to the North Pole, progressively smaller differences in topography become more important in determining temperature.

Often, therefore, the definition of the Arctic depends on the subject and the scientific discipline. Because all biological processes depend on chemophysical reactions, temperature is an important determinant of biological activity. Also, because nearly all food webs ultimately depend on primary producers that usually require light for photosynthesis, the strong seasonal variations in photoperiod are also important for biological activity. For biologists, therefore, definitions that incorporate the sensitivity of flora and fauna to low temperatures and specific photoperiods are particularly appropriate. Thus, the 10° summer isotherm (where the mean monthly temperature is at or below 10 °C) and the northern limit of forests (the latitudinal treeline), both of which represent the southern boundary of the "low Arctic" in Western terminology and the "tundra zone" in Russian terminology, are commonly used to define the Arctic (Figure 1).

The extent of the Arctic is totally dependent on its definition. Using botanical definitions for the Arctic, Bliss and Matveyeva (1992) calculate that it comprises approximately 7.5 million km², which is approximately 5.5% of the earth's land surface. The Arctic stretches over 33° of latitude from 84° N in Greenland to 51° N in Hudson Bay, Canada (see Jonasson *et al.* in Nuttall and Callaghan, 2000). Almost 2 million km² is permanent snow and ice. Distances around the Arctic decrease dramatically toward the North Pole. For example, the circumference of the equator is 40,076 km, and only 13,752 km at the

70° parallel. This has great implications for connectivity between animal and plant populations and species.

The complexity of defining the Arctic is amplified when the region is subdivided into different zones. Although it is clear that the Arctic is not a homogeneous environment, definitions of subzones vary between Eastern and Western scientific traditions (Bliss and Matveyeva, 1992; Walker *et al.*, 2005; Table 1).

Despite these classifications, the 'sub-Arctic' region is often referred to and represents the ecotone between the tundra and taiga and the forest tundra. In fact, there is a continuous gradient of environmental severity within the Arctic from the boreal forest zone at its southern boundary to the polar deserts of the far north, even if this is interrupted in some places by mountain chains and water bodies. Along this gradient, the nature of the species changes from erect woody plants to low-growing herbs, mosses, and lichens, and the complexity of the canopy in vertical and horizontal dimensions decreases from south to north.

Great temperature variations exist throughout the Arctic. From the southern boundary, where the mean July temperature is 10 °C and there are more than 1000 days > 0 °C, there is a decrease to the high Arctic, where the mean July temperature can be less than 2 °C with just greater than 110 day year⁻¹. Precipitation also decreases toward the north, from more than 1000 mm year⁻¹ to approximately 50 mm year⁻¹. Low temperatures and low precipitation exert critical limitations on the productivity of Arctic ecosystems (Jonasson *et al.* in Nuttall and Callaghan, 2000). The net primary production varies from approximately 1 g m⁻² year⁻¹ in polar deserts to 150–800 g m⁻² year⁻¹ in the sub-Arctic. In the low Arctic, values can range between 100 and 1200. Although there is a good correlation between temperature and productivity, the mechanisms are complex. In many areas, it has been suggested that the most important aspect of temperature is indirect in that it constrains the rate of nutrient cycling in cold Arctic soils, thereby resulting in nutrient limitation throughout most of the Arctic (Jonasson *et al.* in Nuttall and Callaghan, 2000).

The great spatial differences in temperature regimes throughout the current Arctic are accompanied by even greater variations over time. Arctic landmasses and oceans are relatively young and have been formed by the migrations of landmasses from southerly latitudes. Also, most of the Arctic's land and oceans have been covered even in summer by ice, but only during the past 1.8 million years. The last glacial period, which ended approximately 10,000 years ago displaced terrestrial, freshwater, and marine species southward from much of the Arctic. A similar process occurred over large lowland areas of the Russian Arctic when they were entirely inundated by the marine transgression (Aleksandrova, 1980; Yurtsev, 1997).

The Arctic's current biota can be seen, therefore, as relatively young and, on land, it can be interpreted as depauperate remnants of previous floras and faunas that existed in pre-glacial eras. For example, forests covered areas of Greenland, Svalbard, and the Canadian high Arctic Archipelago during the Tertiary Period, ending approximately 3 million years ago (this signified a warmer Arctic but also an Arctic landmass that was a few degrees latitude further south). The megafauna, such as

the mammoth, of the Russian Arctic and extensive tundra steppe communities disappeared during the early Holocene.

Current vegetation patterns in the Arctic are to a large extent controlled by the glacial retreat during the Holocene (Raynolds and Walker, 2009), and much of the current Arctic floras immigrated into the Arctic during this period. For instance, on Svalbard, long-distance plant colonization has occurred repeatedly and from several source regions (Alsos *et al.*, 2007). However, some Arctic areas, “refugia” and “nunataks,” remained ice free and supported biota for periods long enough to facilitate the establishment of endemic taxa. The eastern Russian Arctic was largely free of ice during the last ice age and is now associated with many endemic species (CAFF, 1999). Some species, such as *Pedicularis dasyantha* from Svalbard, are thought to have survived in a refugium and then spread outward (Odasz, as quoted by McGraw in Chapin and Körner, 1995).

During the recolonization of the Arctic, the continuity of landmasses, as well as the decreasing longitudinal distances toward the pole, allowed the movement of biota into, out of, and around the Arctic, for example, across the Bering land bridge. This connectivity allowed, and continues to allow, the mobility of many organisms such as marine mammals, migrating caribou, and particularly migratory birds. Such mobility adds considerable complexity to understanding the biodiversity in the Arctic because some of the causal factors are operative when migratory organisms are in other latitudes.

Despite this general connectivity, barriers to dispersal of species occur throughout the Arctic. In Alaska, the Brooks mountain range runs approximately east–west and separates the taiga forest zone to the south from the tundra zone in the north. In the Canadian Arctic, much of the Northwest Territories is an archipelago, and in Greenland, particularly along the east coast, glaciers flowing to the sea interrupt the continuity of ice-free coastal lands, whereas the Greenland ice sheet in general is an effective barrier covering the majority of the country. In Fennoscandia, the mainland is represented

mainly by sub-Arctic areas in the mountains, and high Arctic environments are found only on the Svalbard archipelago. In the Russian Arctic, the Ural Mountains running north–south separate the vast landmass longitudinally. However, on the Taymyr Peninsula, the greatest latitudinal continuity of land reaches into the Arctic.

Patterns of Biodiversity in the Arctic

It is not possible to state the exact number of species in the Arctic because of a lack of taxonomic knowledge (particularly for the Protozoa, Nematoda, terrestrial Oligochaeta, many Acari taxa, and insect families in the orders Diptera, Hymenoptera, and Lepidoptera) and incompatible synonyms used in different countries. Estimating microbial diversity is even more problematic although these molecular techniques are improving the situation. However, some estimates of general species number can be made (Matveyeva and Chernov in Nuttall and Callaghan, 2000; updated in Callaghan *et al.*, 2005, in ACIA, 2005; Table 2).

The number of species in the majority of plant and animal classes that are of importance in the higher Arctic environments amounts, on average, to approximately 2.5% of the worldwide species number for a given taxon (Table 2). The majority of the higher terrestrial faunal taxa are represented in the Arctic, although on a species number basis the Arctic contains less than 1% of the world’s fauna. In comparison, the angiosperms, the most advanced plant taxon, have fewer species in the Arctic than the cryptogams (Table 2). Thus, the Arctic’s biota is not just an extremely impoverished replication of the world’s biota but also has a very distinctive structure as exemplified by the proportions of the highest taxa of plants and animals.

Classes that are well represented in, and are therefore particularly well adapted to, Arctic environments constitute approximately 3–11% or more of global diversity. These include birds, springtails, mosses, and lichens. The largest classes

Table 2 Biodiversity estimates for the Arctic compared with world biota^a

Taxon								
Animals			Plants			Fungi		
Group	Number	% of world biota	Group	Number	% of world biota	Group	Number	% of world biota
Mammals	75	1.7	Angiosperms	2130	0.9	Fungi	2500	2.3

^aModified from Matveyeva and Chernov in Nuttall M and Callaghan TV (2000) *The Arctic: Environment, People, Policy*. Reading, UK: Harwood, and updated in Callaghan TV, Björn LO, Chernov Y, *et al.* (2005) Tundra and polar desert ecosystems. In *ACIA, Arctic Climate Impacts Assessment*, pp. 243–352. Cambridge, UK: Cambridge University Press, and with information kindly provided by Prof. FJA Daniels, University of Muenster, assuming estimates of relative proportions of Dycotyledons to Monocotyledons on one hand, and Mosses to Liverworts on the other, have remained unchanged since the 2005 publication.

^bAmphibians (7), Centipedes (10), Mollusks (3), Annelids (70), and Nematodes (~500).

of global biota (e.g., insects and flowering plants) have the lowest level of representation in the Arctic at 0.4% and 0.7%, respectively. At lower taxonomic levels – orders, families, and genera – some taxa are endemic to the Arctic. For instance, all species of the order of the diving birds Gaviiformes are found in the Arctic.

Although the proportion of various taxa that are found in the Arctic may be very small, there is a common misunderstanding that this equates to low species numbers in Arctic communities (Chapin and Körner, 1995). This is not necessarily the case. For example, the wide ecological distribution of many Arctic plants, together with their small stature, results in high numbers of species per unit area in certain communities. Thus, on Taymyr, Matveyeva (Matveyeva and Chernov, in Nutall and Callaghan, 2000) recorded from 110 to 182 species per sample plot (100 m²). There were 40–50 species within 1 m² and up to 25 species within 0.01 m². Even in the polar desert, approximately 50–60 species were recorded per 25 m² in both the Eurasian and the Canadian Arctic.

As with diversity at the community level, low absolute species numbers do not necessarily equate to low functional diversity within communities. Genetic heterogeneity of ecotypes is a reservoir of genotypic variation on which selection acts, fitness is adjusted, and adaptation becomes fixed (Crawford and Chapman in Callaghan *et al.*, 1995). Sub-specific genetic variation occurs in all aspects of Arctic plants such as physiology, morphology, phenology, growth form, growth rate, and reproductive development (McGraw in Chapin and Körner, 1995). However, only some of these differences can be observed in the field (Murray in Chapin and Körner, 1995), and information on population differentiation based on isoenzyme or DNA analyses is rare compared with, for example, that of temperate latitudes. In addition, the longevity of Arctic plants (Callaghan and Emanuelsson, 1985) and the long periods required for many Arctic plant species to reach a mature growth form from seed imposes severe methodological constraints on partitioning variations in growth forms within a species between phenotypic plasticity and genetic differentiation. However, there are many examples of plant species with high levels of ecotypic differentiation, for example, *Oxyria digyna* (photosynthetic and respiration rates), *Dryas octopetala* and *Saxifraga oppositifolia* (respiration rates and growth form), *Eriophorum vaginatum* and *Carex aquatilis* (phenology), *Phleum alpinum* (growth rates), and *Hylocomium splendens* (growth form).

Possibly as a result of high genetic and ecotypic variability, in combination with low species diversity and a lack of species to occupy available ecological niches in the high Arctic, a phenomenon exists when one and the same species dominates in different communities. Matveyeva and Chernov (in Nutall and Callaghan, 2000) call this “superdominance.” Examples are the lemming *Lemmus sibiricus*, widely distributed in practically all terrestrial habitats from the very wet depressions up to summits in mountains; the crane fly *Tipula carinifrons*; and the circumpolar plants *Arctophila fulva*, *Betula nana sensu lato*, *Carex stans*, *Cassiope tetragona*, *Dryas punctata*, *Dupontia fisheri*, *Eriophorum angustifolium*, *E. vaginatum*, *H. splendens sensu lato*, *Aulacomnium turgidum*, *Drepanocladus uncinatus*, and *Ptilidium ciliare*.

Despite the wide ecological amplitudes of many Arctic species, still strong geographical trends are associated with their distributions. At the species level, two basic types of distributions within the Arctic can be classified: polyzonal and zonal (Table 3). Polyzonal species have wide distributions in both the tundra and the taiga and possibly elsewhere. Zonal Arctic species, omitting topographical distinctions, can be subdivided into hyperarctic, euarctic, hemiarctic, and hypoarctic groups (Table 3; Chernov and Matveyeva in Nutall and Callaghan, 2000). These groups represent a distributional progression from the polar deserts to the taiga boundary described later and are described with examples in Table 3. Furthermore, they provide a useful basis for projecting the sensitivity of a species to climate change in that the polyzonal species are likely to be relatively resilient to change whereas the zonal Arctic hyperarctic species are likely to suffer reductions in appropriate habitats.

The Arctic contains extreme environments – polar deserts, snow, and ice – and these host specially adapted organisms called “extremophiles” (Bell, in press). Ice masses can be considered as ecosystem habitats with two key glacial ecosystems, one inhabiting the glacier surface (the supraglacial ecosystem) and the other at the ice-bed interface (the subglacial ecosystem) (Hodson *et al.*, 2008). The supraglacial ecosystem is characterized by microbes such as bacteria, algae, phytoflagellates, fungi, viruses and occasional rotifers, tardigrades, and diatoms within the snowpack, supraglacial streams, and melt pools (cryoconite holes). Perhaps the most noticeable are the snow algae, which can turn snow packs into a pink color. The subglacial system is dominated by aerobic/anaerobic bacteria and most probably viruses in basal ice/till mixtures and subglacial lakes (Hodson *et al.*, 2008). All these glacial ecosystems are sensitive to climate change. However, whereas rapid, melt-driven habitat changes affect microorganisms in many supraglacial ecosystems, much slower processes affect the subglacial ecosystem.

Even more extreme habitats are presented by permafrost. Large numbers (more than in the soil layers above) of viable ancient microbes are present within permafrost. They have been extracted from depths of 400 m in temperatures of –17 °C (Gilichinsky, 2002). Spore-forming and spore-less bacteria, green algae and cyanobacteria, yeast, and mycelium fungi have been found. Evidence of extracellular enzymes and pigments suggests that many of these organisms are not just viable but also active even though the age of the isolates can be millions of years. These microorganisms are the only organisms that have remained viable over geological time and conceptually, and they could help to resolve fundamental scientific issues such as the periods for which organisms can remain viable on the earth or even on Mars. Climate change could result in the release of some organisms in the surface layers of thawing permafrost with unknown health consequences, whereas permafrost drilling could potentially release the oldest organisms.

Latitudinal Patterns of Diversity

Great changes in biodiversity within the Arctic often reflect sharp thermal gradients that have no analogies in other

Table 3 Diversity changes with latitude in the Arctic region

Category	Distribution	Examples		
		Plants	Birds	Mammals and invertebrates
Polyzonal	Taiga and far to the north in tundra but usually in local habitats and wet depressions	Soil algae; the mosses <i>Hylocomium splendens sensu lato</i> , <i>Aulacomnium turgidum</i> , and <i>Racomitrium lanuginosum</i> ; the liverwort <i>Ptilidium ciliare</i> ; the lichens <i>Cetraria islandica</i> , <i>Psora decipiens</i> , and <i>Cladina rangiferina</i> ; the vascular species <i>Cardamine pratensis</i> , <i>Chrysosplenium alternifolium</i> , and <i>Eriophorum angustifolium</i> ; the sedge <i>Carex duriuscula</i> the herb <i>Helictotrichon krylovii</i> ; the moss <i>Tortula ruralis</i>	The common raven <i>Corvus corax</i> , the peregrine falcon <i>Falco peregrinus</i> , the white wagtail <i>Motacilla alba</i> , and the northern wheatear <i>Oenanthe oenanthe</i>	The wolf <i>Canis lupus</i> , the ermine <i>Mustella ermine</i> , the weasel <i>M. nivalis</i> , the vole <i>Microtus gregalis</i> , and the mite <i>Chiloxanthus pilosus</i>
Zonal boreal	Not abundant and constrained to the south of the Arctic in benign habitats such as river valleys, south-facing slopes, and wet areas	Tree species of <i>Larix</i> ; the orchid <i>Corallorhiza</i> ; the shrub <i>Salix myrtilloides</i> ; the sedges <i>Carex chordorrhiza</i> ; the herbs <i>Allium schoenoprasum</i> , <i>Cortusa matthioli</i> , <i>Galium densiflorum</i> , <i>Sanguisorba officinalis</i> ; and forest mosses <i>Climacium dendroides</i> , <i>Pleurozium shreberi</i> , and <i>Rhytidiadelphus triquetrus</i>	The forest birds <i>Turdus miscus</i> and <i>T. polaris</i> (thrushes); chaff-chaffs <i>Phylloscopus trochilus</i> and <i>P. collybita</i> ; and river ducks <i>Anas acuta</i> , <i>A. penelope</i> , and <i>A. crecca</i>	Reindeer and the wolverine <i>Gulo gulo</i>
Zonal arctic hyperarctic	Polar desert and in the northern-most part of the tundra zone	Almost no plants are restricted to these zones: The following have their highest frequencies there—the grasses <i>Phippsia algida</i> and <i>Poa abbreviata</i> ; the herbs <i>Cerastium regelii</i> , <i>Draba oblongata</i> , <i>D. subcapitata</i> , <i>Saxifraga hyperborea</i> , and <i>S. oppositifolia</i> ; the mosses <i>Dicranoweisia crispula</i> , <i>Bryum tortifolium</i> , <i>Orthothecium chryseum</i> and <i>Seligeria polaris</i> ; and the lichens <i>Cetraria delisei</i> , <i>C. elenkenii</i> , <i>Dactylina ramulosa</i> , <i>D. madreporiformis</i> , and <i>Thamnotia subuliformis</i>	The dovekie <i>Alle alle</i> , the ivory gull <i>Pagophila eburnea</i> , and snipe <i>Calidris alba</i> and <i>C. maritima</i>	Polar bear and the collembolan <i>Vertagopus brevicaudus</i>
Euarctic	Northern part of the tundra zone, rare in the southern part	The dwarf shrubs <i>Salix polaris</i> and <i>S. arctica</i> (this group is relatively small, but it has an important value in the subdivision of the tundra zone into subzones)	The black-bellied plover <i>Squatorola squatorola</i> , the curlew sandpiper <i>Calidris ferruginea</i> , the snowy owl <i>Nyctea scandiaca</i> , and the snow-bunting <i>Plectrophenax nivalis</i>	The lemming <i>Dicrostonyx torquatus</i> and the crane fly <i>Tipula carinifrons</i>

biomes. In the Siberian sector of the tundra zone over a distance of 900 km, the mean July temperature decreases from 12 to 2 °C, whereas in the boreal forest belt, a comparable 10 °C change in mean July temperature occurs over almost 2000 km, a range across which there are three natural life zones. The gradient of summer temperature of 12 °C at the treeline of the Taymyr Peninsula to 2 °C in the polar desert is associated with a decrease in the number of vascular plants in local floras from approximately 250 in the south to approximately 50 in the north. Analogous decreases in plant diversity in Canada also exist (Rannie, 1986). A similar pattern occurs in the animal world, for instance, in day butterflies, beetles and birds (Figure 2), and spiders. At a larger scale, there is a general decrease in biodiversity with an increase in latitude from temperate to Arctic ecosystems (Figure 2).

In the plant kingdom, patterns of decrease in biological diversity toward the North Pole differ among taxa. Some diminish their significance in the biota or even disappear (Ericoids), others change proportionally to the level of general diversity (Fabaceae and Rosaceae), and a third type retain a high level of biological diversity in the Arctic where their proportion becomes higher (Saxifragaceae and Brassicaceae). Not only is there a decrease in plant species and family diversity with increasing latitude, but also the paucity of life forms within the plant kingdom of the Arctic results in a simpler vertical vegetation structure than that of the forested regions further south. In the Arctic, two- or three-layered vegetation, with the height of the tallest shrub layer up to 2 m, changes into the nearly two-dimensional plant cover of polar deserts where most of the biota are concentrated into a thin film of less than 5 cm above the ground and no more than 5 cm below the ground.

Because any species belongs to a particular life (or growth) form (Figure 3), the changes in species composition inevitably lead to changes in the proportion of life forms in a wide sense. The proportion of rooted species (flowering plants) that control their water content to merely adnate species (cryptogams) decreases from approximately 1:2 at the treeline to approximately 1:5 in the polar desert. Tall shrubs are common in the south of the tundra, but absent in the north. Dwarf shrubs are widely spread throughout the tundra zone, but absent in polar desert ecosystems. The proportion of long rhizomatous herbs decreases whereas that of tap-rooted plants increases in the northern direction. Loose caespitose species are replaced by dense tufted cushions or mat-forming species (Figure 3). Within a species, there is also a tendency to form more compact growth forms in the north compared to in the south.

Latitudinal patterns of biodiversity within the Arctic may reflect global trends. Passerines and other bird taxa that are important in the tropics (e.g., kingfishers, woodpeckers, parrots, hummingbirds, and pigeons) decrease successively as a proportion of the avifauna from the equator to the poles. Passerine birds comprise approximately 60% of the avifauna in temperate and tropical forests, approximately 50% up to the northern taiga landscapes, 40% in forest-tundra, and 20% in the northern part of the tundra zone. In contrast, the proportion of Charadriiformes (40%) and geese-like birds (20%) in the Arctic avifauna is high and decreases toward the south. Charadriiformes are reduced to 20% in the north taiga and 10% in the south, and they contribute only 5% in the tropics.

Circumpolar Diversity

The Arctic's biota have a relatively large number and proportion of circumpolar species compared with circumboreal

Figure 3 Growth forms of tundra plants, with example species. Plant functional type classifications basically follow the growth forms depicted and usually do not specify any particular function even though different classifications might be appropriate for individual functions. Reproduced from Webber PJ (1978) Spatial and temporal variation of the vegetation and its productivity. In: Tieszen LL (ed.) *Vegetation and Production Ecology of an Alaskan Arctic Tundra*, pp. 37–112. New York: Springer.

species. One of the obvious reasons for this is the decreasing circumference of latitudes toward the poles. Circumpolar vascular plants comprise approximately 45–50% of the extant flora in the south, 60–65% in the north of the tundra zone, and more than 70% in the polar desert.

Less than half of the Arctic birds may be considered circumpolar because many species formally considered as circumpolar have large gaps in their distribution. Thus, approximately 20% of the Arctic avifauna are true circumpolar species, and only 10% of the tundra terrestrial fauna are circumpolar species. Only 2 of 50 tundra *Tipulidae* species have true circumpolar distributions. Only 1 species is conditionally circumpolar among approximately 40 leaf-eater beetles (*Chrysomelidae*) known in the Arctic. In two very common plant genera, *Saxifraga* and *Draba*, each of which includes approximately 40 species in the Arctic, only 25% (10 in each) have true circumpolar distributions. The rich genus *Pedicularis* has 6 circumpolar species out of 24, but 5 of these have large gaps in Europe, Greenland, or eastern North America. In the *Ranunculus* genus, 9 of 25 species are circumpolar. Only 1 of the 10 species of *Dryas* in the Arctic, *D. punctata sensu stricto*, has a true circumpolar distribution.

Species that form monotypic genera have the most pronounced circumpolar distribution. Examples from the animal world are arctic fox (*Vulpes lagopus*), snowy owl (*Nyctea scandiaca*), old squaw duck (*Clangula hyemalis*), and calliphorid (*Boreellus atriceps*) and from the plant world the grasses *Arctophila fulva*, *Dupontia fisheri*, and *Pleur-pogon sabinei*; the herbs *Koenigia islandica* and *Oxyria digyna*. The two latter species have enormous geographic ranges, being circumpolar and with extensions far south: *K. islandica* is bipolar.

Most species have distributions narrower than circumpolar. In general, there are five main types of longitudinal distribution: Species can have (1) true circumpolar distribution or, if represented on both the North American and the Eurasian continent, they can have (2) amphi-Atlantic or (3) amphi-Pacific (Beringian) distributions or they can occur only on (4) Eurasian or on (5) North American continents. Within each continent, there are an additional five subregions, giving 10 zonations in total (Porsild, 1959): They can have a wide geographic range (Eurasian species or North American species) or can occur in a more restricted area (e.g., Siberian or Alaskan species).

Figure 4 Local topography. Small-scale variations in topography determine the patterns of plant communities. This idealized mesotopographic gradient shows five microsites commonly found in Arctic landscapes (Walker *et al.*, 2002). Reproduced from Walker DA, Raynolds MK, Daniëls FJA, *et al.* (2005) The Circumpolar Arctic vegetation map. *Journal of Vegetation Science* 16: 267–282.

Effect of Topography on Biodiversity

The macrorelief represented by Arctic lowlands and mountain ranges is the main cause of interlandscape diversity and imposes altitudinal biodiversity patterns on longitudinal and latitudinal ones. The diversity of mesorelief forms is responsible for the diversity of the vegetation at the intralandscape level through their impacts on local temperature and snow accumulation. Throughout a range of tundra environments, there are recurring patterns in the distribution of diversity relative to topography (Figure 4). Using Russian terminology, zonal (i.e., mesic) tundra communities occupy the central environmental position within the landscape, namely, the “plakor” or watershed. These communities consist of continuous lichen–moss cover (pleurocarpous green mosses and fruticose lichens) with either a more or less sparse layer of shrubs, dwarf shrubs, sedges, and cotton grasses in the south or grasses and dicotyledonous herbs in the north. These communities have the richest species composition and are considered the true tundra communities for a given site. In addition, there is a rich diversity of intrazonal communities with fewer species and life forms developing along environmental gradients that deviate from zonal communities, including mires (without fruticose lichens), grasslands on south-facing slopes (with only few mosses), snowbed vegetation on the north-facing slopes, dwarf shrub heaths on fellfields (with few mosses), dense shrub thickets in deep valleys, and salt marshes.

Although different types of vegetation can be distinguished within a landscape, even greater diversity in vegetation pattern can occur over shorter distances due to nanorelief (e.g., patterned ground). A host of forms of patterned ground are found (Washburn, 1956). Within a given patterned ground feature, substrate stability can vary widely, influencing disturbance, soil nutrient availability, soil moisture, microclimate, and thickness of the active layer above permafrost. The relief of the patterned ground feature may influence the duration and height of the snow within a few square meters, for example, between hummocks and hollows. The extremely localized ability of Arctic plants to influence

microenvironments leads to a great complexity of plant diversity, biomass, net primary production, and soil flora and fauna characteristics with small (> 10 cm) differences in relief.

An additional resource increasing landscape diversity is the presence of diversity ‘focal points’ (Walker, in Chapin and Körner, 1995) or ‘oases’ (Edlund and Alt, 1989; Svoboda and Freedman, 1994). Moist areas below snowbeds in the Canadian polar deserts have a plant cover many orders of magnitude higher than that of the surrounding barrens and contain most of the local plant species diversity. Pingos, with their dome shape, steep slopes of diverse exposures, and gravel and sand substrate, are also ‘hot spots of diversity’ on the flat Alaskan coastal plain dominated by tussock tundra (Walker, in Chapin and Körner, 1995).

Localized topographical extremes can be associated with extreme species distribution outliers. Deep valleys with thick snow cover in winter and warm weather in summer at latitude 75° N on Taymyr have dense willow thickets of *Salix lanata* up to 2 m tall. Warm-water springs in Alaska, Chukotka, and middle-west Greenland create localized warm microclimates, and many stands in the surroundings of these hot springs support extreme range disjunctions of southern, even boreal, species. Examples include stands of *Populus balsamifera* in the northern foothills of the Brooks Range and the Chukotka Peninsula, well to the north of the treeline; ferns, orchids, and umbellifers near warm springs on Disko Island; and dwarf shrubs in some inner fjord areas of Svalbard. Steep south-facing river banks combine warm and well-drained habitats with the possibility of migration along the river corridor and are another focal point of community diversity, often supporting trees within the tundra. Animals also create diversity hot spots, when they are dead, by providing nutrients and moisture in polar deserts and fellfields and, when they are alive, by bringing back nutrients to their nesting places or dens. Examples are bird cliff communities, fox and wolf dens, and lemming gardens. Such outliers represent potential “inocula” for recolonization (*see Threats to Biodiversity in the Arctic*) and plant community change in a future warmer climate and support animal species with more southerly

distributions. This process may have occurred approximately 12,000 or 13,000 years ago in Beringia, when birch rapidly spread and created a 'birch zone.'

Controls of Biodiversity

A series of filters has selected, and is selecting, species and genotypes that occur in the Arctic (Walker, in Chapin and Körner, 1995). The first filter is the presence of a species in the region, the second set of filters is the biogeography of species within the Arctic, and the third set of filters is internal filters within communities and the environment. Körner (in Chapin and Körner, 1995) adds a time dimension to the geographical filters. For example, the current range of species and communities in the Arctic has been determined by survivors from the thinning of past populations and floras during glacial periods together with the species that immigrated into the Arctic during the Holocene. In his Alpine examples, Körner describes a second filter, grazing and freezing temperatures, and a third filter that acts at the microscale and specifically selects plant species that can tolerate certain microclimates, soil disturbance levels, and moisture regimes.

In the Arctic, during the Pleistocene, it could be argued that the first filter was environmental in that only freezing-tolerant plant species could survive in a region that became 'Arctic' in character. Later, during the Holocene, the next set of filters could be seen as relating to migration and dispersal abilities in that many species followed the retreating ice margins northward, whereas some glacial relicts spread outward from their refugia. It is possible that this filter could at least partially explain the high abundance of cryptogams, which have easily dispersed spores, relative to vascular plants in the Arctic. In general, however, it can be assumed that the main set of filters on current Arctic biodiversity is environmental rather than constraints on migration and the 'available species pool' (see, e.g., Alsos *et al.*, 2007). This assumption is also supported because, for example, latitudinal treelines are often situated more to the south now than during the earlier Holocene (although trees never reached the high Arctic, even during the climatic optimum of the Holocene). Also, herbivore diversity and population sizes are limited by low primary production resulting primarily from low nutrient availability. Any local increase in nutrient availability (e.g., through animal activity) dramatically stimulates biodiversity and productivity.

The next set of filters, as suggested by Körner, act at the microscale and consist of numerous interactions among plants in communities, between plants and herbivores, and between all organisms and the microenvironment. These fine-scale filters select for organisms that are preadapted to Arctic environments or that have developed specific adaptations. Among the animals, preadaptations can be seen in traits common in boreal forest animals. In plants, preadaptations are particularly evident in those with Arctic-Alpine distributions (i.e., with populations in Alpine areas to the south of the Arctic) and in those from nutrient-poor bogs of the temperate region. Specific adaptations of plants to the Arctic environment have been considered to be few. A constraint on adaptation rate has been the generally young nature of the Arctic flora, the longevity of many plants, and the sporadic

successful completion of reproduction and seedling recruitment in areas of closed vegetation (Callaghan and Emanuelsson, 1985).

The fine-scale filters on biodiversity arising from biotic interactions were mentioned earlier. Plant competition is not thought to be a major force displacing species in the Arctic. Indeed, species removal experiments often result in little compensatory growth of remaining species, though the shrub species dwarf birch *B. nana* seems capable of displacing other shrubs in a warmer Arctic (Bret-Harte *et al.*, 2001). Instead, facilitation and succession are important and might explain to some extent the similarity of plant aggregations throughout large areas of the Arctic. If there were any competitive 'tensions' within these aggregations, they would be expected to have broken down over time or over geographical ranges.

Herbivory is only sometimes a filter on biodiversity. Perhaps in general, herbivores do not eat particular plant species to extinction and, indeed, can stimulate plant diversity. Also, in some cases, herbivores may act as buffers against other, for example, climate-induced, changes of the vegetation (Post and Pedersen, 2008; Olofsson *et al.*, 2009). In other cases, such as grazing by snow geese in the Hudson Bay area, high population pressure can lead to ecological cascades ending with loss of plant populations and ultimately soil erosion. Similar dramatic impacts on vegetation can occur when population peaks of two different herbivores, both feeding on the same plant, occur within a short period of time. Analogs of tundra vegetation in Fennoscandia can be produced when sub-Arctic birch forests are defoliated by insects and regenerating trees are browsed by reindeer. Also, browsers such as the megafauna of the Pleistocene and early Holocene had the ability to maintain open vegetation (Zhimov *et al.*, in Chapin and Körner, 1995), whereas grazers can control dominance in plant communities, for example, by suppressing moss growth. Although such impacts can be dramatic at the local scale, the generally wide distributions of many Arctic species ensure survival of the species. Survival of rare species and ecotypes, however, has a greater risk.

Consequences of Biodiversity

Environmental Consequences of Biodiversity

One way in which the importance of biodiversity within processes can be readily considered is by understanding the potential impact of biodiversity decline. Primary successional processes are indicative of the potential impact of biodiversity loss. One of the most thoroughly studied successional series within the Arctic is that present at Glacier Bay, Alaska (Chapin *et al.*, 1994). The retreat of the glaciers during the past 200 years has led to the development of a series of communities whose spatial arrangement can be considered analogous to a sequence through time. At the foot of retreating glaciers is a harsh environment of exposed glacial till that lacks soil organic matter and soil nutrients, and is a potential zone of drought. Mats of nitrogen-fixing cyanobacteria, lichens, and liverworts, with scattered forbs (e.g., the nitrogen-fixing *Dryas drummondii*), colonize these environments. The process of pedogenesis, involving the accumulation of organic matter

and plant-available soil nutrients, then proceeds and the succession sequence passes through many stages from alder woodland (*Alnus sinuata*) to sitka spruce (*Picea sitchensis*) forest. The seedlings of key species from each successional stage at Glacier Bay were found to germinate more readily within the preceding successional stage than within that of their own (Chapin *et al.*, 1994). Every step of the successional process enhances the development of species dominant within the next stage. Given the loss of any individual step within this series, the composition of the community may develop along an entirely different trajectory, or the environment may never develop beyond a given point.

The nature of Arctic environments is such that events leading to the initiation of primary succession, for example, ice-based processes such as frost heave, avalanche, and debris flows and high runoff due to permafrost-impeded drainage, are common. For any site undergoing primary succession, the availability of propagules of primary colonizers within that area is essential. An underlying level of diversity is necessary throughout the environment for appropriate colonizer species to be within the range of disturbance events. For example, in the Alaskan tundra, gravel pads and borrow pits are often initially colonized by species from nearby riparian systems. Without habitat diversity at the landscape level, these colonizing species would be absent. Therefore, both the distribution and the absolute number of organisms are important for ecosystem function. Organisms may maintain the habitat diversity of Arctic systems. The activity of burrowing animals such as ground squirrels, lemmings, or Arctic foxes may provide exposed areas of disturbed soil that act as potential refugia for plant primary colonizers and faunal diversity, thus promoting floral diversity. Another example is animals acting as seed dispersers, thereby aiding not only dispersion but also biodiversity in general (Bruun *et al.*, 2008).

As succession proceeds, the potential for interaction between organisms increases because their zones of influence are more likely to overlap with increasing organism density (this is especially true of plants). Because of an increase in the number of species, the potential complexity of interactions within a community also increases. Therefore, there may be a parallel increase in the level of biodiversity and the degree and complexity of interactions between individuals. This type of pattern might be found along the latitudinal gradient from high Arctic polar semidesert toward more productive tundra environments.

Types of interaction include direct resource-based interactions (e.g., competition) and indirect interactions, possibly involving higher trophic levels. For example, there is evidence that herbivores may encourage the development of vascular plants by preventing the formation of dense moss mats in certain tundra environments (Zhimov *et al.*, in Chapin and Körner, 1995; Van der Wal and Brooker, 2004). Because of the mobile nature of larger herbivores (e.g., reindeer and musk ox), their importance in the functioning of a community at any given time may not be clear. As in the case of plant primary colonizers, the key role that they play, and their importance in terms of maintaining diversity at both the species and the community level, may be apparent only at particular points in time or space.

Facilitative interactions may be of particular importance within Arctic communities. In the case of plant interactions,

Figure 5 Impact of mosses in determining the growth of vascular plants in the high Arctic (an example is the grass *Poa arctica* growing in cushions of the moss *Drepanocladus uncinatus*). The impact of the moss on the growth of the grass, when compared with the grass growing outside moss cushions, is equivalent to growing the grass under plastic greenhouses with nutrient addition (+T and N) (reproduced from Press MC, Callaghan TV, and Lee JA (1998) How will European arctic ecosystems respond to projected global environmental change? *Ambio* 27: 306–311).

facilitation may act through the amelioration of environmental severity and may occur within all successional stages, including mature communities. Facilitative plant species may be keystone species within an environment; for example, in areas of frost heave-disturbed scree, the growth of spreading plant species with persistent nets of rhizomes or roots has been shown to stabilize the scree and to allow the development of other plant species within the stabilized zone. A critical factor in this case is the morphology of the colonizing plant. Other types of plant growth form may have different facilitative effects. Although all plants may provide shelter to their neighbors, certain species and growth forms, especially cushion plants, can develop in the absence of this initial shelter and can raise temperature differentials between their meristems and the air by more than 25 °C. They subsequently provide shelter for others. In one Alpine example, five species of cushion plant, including *Silene acaulis*, together 'hosted' 93 other species of plants. In another example, grasses growing in moss cushions in the high Arctic grew dramatically faster than those growing outside moss cushions (Figure 5). Diversity of form (Figure 3) is therefore perhaps one aspect of Arctic biodiversity that may be critical for ecosystem function.

Differences in plant growth form also strongly affect the movement of resources within an environment. Spreading rhizomatous species that maintain physiological connections between individuals may move nutrient resources away from localized resource-rich areas. Species with spreading root systems but a localized canopy may in turn concentrate resources within a given area. Similarly, differences in the behavior of animals may also lead to variability in resource distribution and resource movement throughout the environment. During the winter period when their grazing is confined to roots, rhizomes, and the stem bases, lemmings can accumulate within their nesting areas small reservoirs of nutrients in plant tissue and droppings. Other grazing species such as geese

and muskoxen may redistribute nutrients throughout the environment.

Not only are nutrient distribution processes dependent on the variability in life form, and hence diversity, but also nutrient cycling and soil conditions (e.g., temperature, moisture, and pH) may be strongly related to the diversity of organisms within an ecosystem. Hobbie (in Chapin and Körner, 1995) describes how differences in plant traits may directly and indirectly influence biogeochemical processes within tundra plant communities. For example, species with high productivity rates (generally deciduous and graminoid species) may increase the rate of nutrient turnover, woody species may increase the sequestration of carbon, and graminoid species may attract herbivores and increase the degree of herbivore nutrient cycling. Interspecific variability in rooting depth and leaf area influences soil moisture conditions, which in turn may influence soil nutrient availability, soil biota diversity, ion uptake, and soil pH. Leaf litter tissue quality differences may also influence soil microbial processes and decomposition rates. Mixtures of litter from more than one Arctic plant growth form, particularly hemiparasitic herbs and dwarf shrubs, have been shown to decompose at a faster rate than single-species litters (Questaed *et al.*, 2002). The diversity of a plant community will therefore have important consequences for soil environmental conditions and terrestrial nutrient cycling, which is a major constraint on productivity of Arctic ecosystems.

Species diversity may also affect atmospheric environmental conditions by influencing soil-atmosphere exchange processes. Verville *et al.* (1998) found that sedges contribute to methane emission from Arctic wet meadow communities by acting as a conduit for methane release from anaerobic soils (rather than by producing methane directly). In contrast, mosses tend to limit the evolution of methane (Figure 6).

Natural Resources and Environmental Exploitation

An analysis of ecosystem services from the Arctic was presented by Chapin *et al.*, 2005 during the Millennium Assessment of Ecosystems. The Arctic's ecosystems are important for both their provisioning services (e.g., food) and their regulatory services (e.g., drawdown and storage of atmospheric carbon). At the most simplistic level, biodiversity can be considered a natural resource. One key future of Arctic biodiversity as a resource is its unique components, that is, species (and processes) that are confined to Arctic ecosystems. However, existence per se is not commonly considered to be a resource, and the tendency is to regard resources as items for exploitation by humans, either currently or in the future.

Certain types of human exploitation of Arctic natural resources are limited by biodiversity and by productivity, namely, those in which an organic crop is removed from the environment. Biodiversity determines the number of resources available, and productivity limits the rate at which they can be exploited. For humans to live within the Arctic using extant natural resources, they must travel over a wide area to obtain and concentrate sufficient energy, nutrients, and raw materials. The Saami people of northern Fennoscandia follow their reindeer because productivity in general is very low and it is necessary for the reindeer herds to move over a vast area in order to obtain

Figure 6 Methane and carbon dioxide fluxes in short-term species removal plots in wet meadow tundra. Sedges acted as a conduit for methane emission and carbon dioxide uptake: Mosses did not. *Statistically significant differences among species-removal treatments ($p=0.05$). Reproduced from Verville JH, Hobbie SE, Chapin III FS, and Hooper DU (1998) Response of tundra CH₄ and CO₂ flux to manipulation of temperature and vegetation. *Biogeochemistry* 43(3): 215–235.

sufficient resources. This is true both for the semidomesticated reindeer herds of the Saami and for the wild caribou herds of North America. One impact of low biodiversity in this context may be the necessity of exploiting one species intensively, such as the Saami exploitation of reindeer, rather than being able to switch exploitation between species on a seasonal basis.

Nonindigenous human exploitation of wildlife has involved hunting to accumulate raw material for manufacturing processes (e.g., furs and blubber). The replacement of many animal-derived products with synthetic materials derived from oil has reduced the pressure on Arctic animal populations. However, hunting of Arctic wildlife still occurs, either by indigenous peoples, such as the Saami or Inuit, or for sport. This latter type of hunting is just one particular branch of the development of tourism within the Arctic. Ecotourism depends heavily on the wildlife of the Arctic. The biodiversity of the Arctic, including unique Arctic species, and the paucity of species and barren nature of high-latitude Arctic systems in particular (i.e., their inherently low biodiversity) may be features of Arctic environments that are attractive to visitors. In this case, biodiversity can be an exploitable resource, and as ecotourism develops, perhaps the monetary value attached to the biodiversity of the Arctic will increase.

A more intangible natural resource dependent on Arctic biodiversity is the potential for future acquisition of knowledge. The low biodiversity and process simplicity within Arctic ecosystems makes them a valuable resource for testing ecological theories. Arctic ecosystems may provide a second type of scientific resource, that is, they might contain undiscovered or unrecognized useful natural substances. Although the low biodiversity of Arctic ecosystems suggests that the number of possibly useful substances is less than that in diverse ecosystems (e.g., rainforest), unique substances may be found that have evolved in response to the Arctic environment. For example, it may be that the Arctic provides humans with a source of natural antifreeze chemicals. Similarly, the mechanism whereby some Arctic species can tolerate extreme anoxia might be important in understanding the problems associated with the susceptibility of some trees and crops to waterlogging.

Mineral resources are another natural product extracted from Arctic environments. However, in this case the problem of exploitation is not one of low biodiversity but rather of exploiting the resources without damage to biodiversity, as discussed in the following section.

Threats to Biodiversity in the Arctic

The Arctic is currently undergoing rapid changes: cultural and sociological changes resulting in exploitation of natural and nonrenewable resources, changes in climate, and changes in pollution – both local and transboundary (Nuttall and Callaghan, 2000; Callaghan *et al.*, 2005; Post *et al.*, 2009; Callaghan and Tweedie, 2011). Many of these changes are predicted to accelerate in the future, and these have implications for changes in biodiversity within the Arctic.

Extractive industries (oil, nickel, etc.) have resulted in large local impacts on species, including reductions in the diversity of soil microorganisms (Evdokimova, in Callaghan *et al.*, 1995). Examples of impacts of mineral extraction are found in towns of the Kola Peninsula, but there has been surprising resilience of the vegetation in that pollution-tolerant forms are being actively selected for (M. Kozlov, personal communication). Oil spills in Alaska and Russia have had dramatic effects on local populations of both plants and animals. However, the large and widespread distributions of Arctic biota provide a system in which changes in biodiversity from this source over wide areas are unlikely. More serious is the slow recovery potential of Arctic vegetation that exacerbates disturbances to ecosystems.

Harvesting of natural resources on land in the Arctic consists mainly of hunting, collecting (e.g., berries), and reindeer husbandry. Effects of hunting have probably had serious impacts on a small proportion of Arctic biota over the Holocene, and it is widely debated whether northern megafauna, such as the mammoth, were hunted to extinction at the beginning of the Holocene. Within the past 300 years, hunting has probably hastened the demise of the great auk, and following the advent of firearms in the north, wolf populations have been reduced to just a few in the sub-Arctic of Fennoscandia. Currently, international agreements protect some species such as polar bear and some subpopulations have increased. However,

the health of many species of birds that migrate to the Arctic is determined more by hunting practices in the overwintering grounds than in the Arctic: This is more difficult to legislate.

Changes in reindeer husbandry practices in Fennoscandia during the past 300–400 years from hunting to herding and, recently, from herding to almost farming in some areas have had impacts on predators (hunted by husbanders) over large areas and on grazing pasture productivity and biodiversity. Restrictions on the nomadic lifestyles of reindeer husbanders both in Fennoscandia (due, for example, to constraints of national boundaries) and in areas of the Russian Arctic (due to imposition of a sedentary lifestyle for women and children) have resulted in large-scale impacts on vegetation with an often dramatic reduction in lichen cover. Changes in lichen biodiversity remain to be documented but are likely to be pronounced.

Pollution in the Arctic is still generally less than in more southerly regions, and the pathways of pollutants into the Arctic and their concentrations within Arctic biota have been well documented recently (Reiersen, in Nuttall and Callaghan, 2000). However, little is known about the sensitivity of Arctic biota to the wide range of pollutants that are found there.

During the 1.8 million years of the Pleistocene, the Arctic has undergone severe climatic fluctuations associated with glacial and interglacial periods. Even within the last interglacial period of the Holocene, climate has changed greatly, resulting in a current cool period associated with lower and more southerly treelines in many places in the Arctic than found in the early Holocene. Since the Little Ice Age, however, which ended in the north Atlantic region approximately 150 years ago, mean annual temperatures have been increasing. Arctic climate has now entered a unique period relative to the instrumental record and, in the case of summer temperatures, relative to 2000-year reconstructions of past variations: This trend is expected to continue (Walsh *et al.*, 2011). Analysis of *in situ* and satellite data shows evidence of different regional snow cover responses to this warming and increasing winter precipitation over the past 40–50 years. In the past decades, sea ice has been diminishing, which adds to the warming of adjacent terrestrial environments (Bhatt *et al.*, 2010). The warming has been followed by an increase in the ‘greenness index’ of vegetation especially in the low Arctic, as seen by satellite images, which suggests an increase in the growing season of approximately 11 days over the past 20 years. The recent increases in temperature in the Arctic have been associated with increased pest outbreaks in the taiga, increased frequency of forest fires, and a warming of permafrost with an increase in disturbance events (ACIA, 2005; AMAP, 2011).

General circulation models that predict future climates for various concentrations of greenhouse gases all agree that future warming will be greatest in the Arctic, and particularly during wintertime. Because of the strong correlations between biodiversity and temperature discussed previously (see Latitudinal Patterns of Diversity), it is expected that future warming will have a large impact on biodiversity in the Arctic. Experiments in a range of Arctic habitats that simulate warmer conditions show that one of the first effects of warming on plant communities is a change in the dominance of vascular plant species existing when the manipulations started and an

increase in biomass (Chapin *et al.*, 1995; Press *et al.*, 1998; Arft *et al.*, 1999). However, as the vascular plants increase in biomass, lichen biomass and cover decrease, and some moss species (e.g., *Hylocomum splendens*) also decrease in abundance. In the case of lichens, the decreases seen in the experiments parallel decreases found along natural geographical gradients of temperature. The major implications of the experiments are therefore that, over the medium term, warming will change the dominance among vascular plant species, the abundance of lichens and mosses will decrease, and the immigration of more southerly species will happen. Over the longer term, clearly, biodiversity of vascular plants will increase but that of cryptogams will decrease. In addition to this decrease in lichens is the impact of changing reindeer husbandry discussed previously (see Natural Resources and Environmental Exploitation). Overall, the Arctic's important role as a reserve of primitive plants is threatened, and the great cover of lichens in the Arctic will have an effect on their biodiversity at a global level.

In contrast to predicted decreases in biodiversity of the mosses and lichens, warming may increase diversity of all plant groups in some places. Glacier forefield expansion as a result of glacier retreat during warming and the open ground of polar deserts and semideserts offer open niches for the establishment of new plants. Because colonization of these habitats is usually by seeds and spores, it can expand the local species and sub-specific genetic diversity. This is in marked contrast to closed areas of vegetation in the mid- and sub-Arctic, where plant establishment is mainly via clonal growth. However, even here, increases in disturbance due to thawing permafrost are likely to open up niches and allow new genets to establish.

Current Status of Arctic Biodiversity

The Conservation of Arctic Flora and Fauna working group of the Arctic Council has initiated a circumpolar assessment of the Arctic biodiversity, and some important findings have already been presented in the overview report *Arctic Biodiversity Trends 2010: Selected Indicators of Change* (Conservation of Arctic Flora and Fauna, 2010). The assessment reports that the unique Arctic habitats are changing rapidly and that this will have severe implications for the entire Arctic. Many populations of the selected Arctic species examined are seemingly stable or increasing, including some of the more abundant seabirds, such as common eiders (*Somateria mollissima*). However, other species central to the Arctic are declining, including reindeer (caribou) and lemmings. Also, some important geographical patterns emerged from the assessment, and whereas the high Arctic vertebrates are declining markedly, vertebrates living in the low Arctic and sub-Arctic have relatively stable or increasing populations. Similar differences were observed when comparing the terrestrial, limnic, and marine biomes, and whereas vertebrate species in the terrestrial biome generally declined, vertebrates in the limnic and marine biomes increased. The Arctic Biodiversity Assessment has identified multiple external stressors impacting the Arctic's diversity, including human exploitation and contamination, but emphasises that the changing climate is emerging as the single most important stressor of Arctic biodiversity.

Another recent assessment of changing Arctic ecosystems and biodiversity is the International Polar Year Project "Back to the Future" in which multidecadal changes were recorded by site revisits and data retrieval (Callaghan and Tweedie, 2011). General patterns were hard to identify: Biodiversity in some areas had remained surprisingly stable, whereas in others, dramatic increases in cover and immigration of a thermophilic species were seen (Callaghan *et al.*, 2011, in Callaghan and Tweedie, 2011). The greatest responses were usually in the woody species, in line with the "shrubbification" of the tundra (Sturm *et al.*, 2001; Tape *et al.*, 2006). Although the sample size was low, a drying pattern was seen in which, for example, ponds had diminished in size. This is characteristic of many areas of the Arctic, while waterlogging occurs in others. Although the net balance of these two processes is critically important in determining future biodiversity, ecosystem services, and biogeochemical cycling, the likely balance is not yet known. An important conclusion of the study is that local factors can override the general climatic controls on diversity, range extension, cover, and productivity of plants. For example, Van Bogaert *et al.* (2011) demonstrated that treeline could relocate upward and downward and remain stable all within the same area experiencing the same climatic changes. In this case, the local controls were release from reindeer herding pressure leading to an upward movement of the treeline, insect pest outbreaks that lowered the treeline, and steep rocky slopes that resulted in a stable treeline. Though the Arctic Biodiversity Assessment and the Back to the Future Projects have made substantial progress in evaluating changing biodiversity of the Arctic, the thorough assessment of the Arctic's biodiversity is hampered by the lack of sufficient data, even for charismatic species such as the polar bear. The Arctic Council initiative Circumpolar Biodiversity Monitoring Program (CBMP; <http://cbmp.arcticportal.org/>) is therefore a cornerstone in the effort to conserve Arctic biodiversity through the development of long-term programs for monitoring the biodiversity in the Arctic.

Conclusion

Although biodiversity in the Arctic is low compared with that in other regions, a surprisingly varied array of landscapes, ecosystems, species, ecotypes, and topographic micropatterns exist. Relationships between diversity and environment are superficially simple because land-use impacts are relatively few in the Arctic. However, beneath the surface, interactions between the snow patterns and low temperatures of the Arctic and its biota are complex: Temperature and snow have many direct effects on the biota but also control nutrient cycling in cold soils, which severely constrains the abundance of vascular plant species and the organisms that depend on them. Importantly, interactions between plants and climate are bi-directional: Plant growth forms facilitate dramatic differentials to occur between plant and air temperatures, whereas tundra soils have sequestered the greenhouse gas carbon dioxide throughout much of the Arctic. Currently, rapid sociological and environmental changes are occurring in the Arctic. Although low biodiversity is compensated for to some extent by large and widespread populations, the vast wilderness areas are nevertheless under numerous threats. Our major challenge is to further document (*Conservation of Arctic Flora and Fauna*, 2001, 2010) and monitor the biota in the remote Arctic wildernesses and to understand both how biodiversity patterns are formed and how they contribute to the functioning of ecosystems. Only then can the conservation strategies be established that can cope with rapid environmental change. The Arctic Biodiversity Assessment and the CBMP are important steps toward a common strategy for the conservation of Arctic biodiversity.

Glossary

Angiosperms Flowering vascular plants in which the seeds, which are produced from the ovules of the flowers, are enclosed in fruits developed from the matured ovaries; the largest class of vascular plants, as opposed to cryptogams (mosses, etc., which do not produce seeds) and conifers (in which the seeds are not enclosed in fruits).

Biodiversity Biological diversity, i.e., the variety of living organisms in an area, including the variety in genes, species, functional types of organisms, and ecosystems.

Biome A major terrestrial ecological community and landscape type, characterized by more or less uniform physiognomy of its potential natural vegetation and with characteristic fauna and flora, such as the tropical rainforest, the warm deserts, or the temperate grasslands.

Boreal Pertaining to the northern high latitudes (but not polar), regions which contain large continental landmasses and thus continental climates with moderate summers but long, severely cold winters (from Greek *boreas*, the north wind).

Ecosystem A community of organisms (plants, animals, and microbes) and their physical environment interacting as an ecological unit, such as a lake, a wetland, a forest, or an agricultural landscape.

Endemic Occurring only within a comparatively restricted geographic range within a specific region.

Global circulation The regular global circulation pattern of the earth's atmosphere, which generates the world's basic climate types; the system involves an Intertropical Convergence zone of low pressure near the equator, subtropical high-pressure belts near the Tropics of Cancer and Capricorn, trade winds flowing from these

high-pressure belts toward the equatorial low, and westerly winds in the midlatitudes.

Monsoon system A wind system covering the eastern half of Asia in which winter cooling of the large landmass produces strong, stable high pressure, with clear skies and outward flow of cold, dry air, and summer warming produces low pressure, drawing wet air masses, with clouds and rain, inward from the adjacent oceans.

Pleistocene glaciation The expansion of ice sheets over the large northern continents, especially northern Europe and North America (excluding the northwest) during the "Ice Ages."

Potential natural vegetation The vegetation cover which would develop naturally in an area and become stable (not replaced by a subsequent stage) if all outside disturbances were eliminated.

Species richness The total number of species of an area or ecosystem.

Temperate Pertaining to the climates and landscapes of the midlatitude regions, which are seasonally warmer and cooler, with winter frost even in most coastal areas and at least partial dormancy or collapse of the vegetation.

Tropical Astronomically, the region lying between the Tropic of Cancer ($23\frac{1}{2}^{\circ}$ N) and Tropic of Capricorn ($23\frac{1}{2}^{\circ}$ S); more generally, involving the climates and landscapes characteristic of this region, which are essentially frost free in the lowlands and permit biological activity as long as water is available.

Vegetation The total plant cover of an area.

Zonation The tendency of climate, soil, and natural landscape types to occur in distinct latitudinal zones (e.g., tropical, subtropical, and temperate), as generated by the global atmospheric circulation system.

Introduction

Asia the world's largest continent, extending from the Mediterranean Sea in the west to the Japanese Archipelago in the east, and from polar landscapes in northern Siberia to hot deserts in the southwest and tropical regions south of the Himalaya and China. Tropical Asia includes perhumid equatorial rainforest climates as well as seasonally wet and dry tropical savannas, raingreen woodlands, and monsoon forests, all extending to some degree from India to the Philippines and East Indies. Dry regions of Asia include an eastward extension of the hot, subtropical Sahara desert into southwestern Asia, large expanses of higher latitude interior deserts with cold winters, and also a small 'mediterranean' region and an east-west strip of temperate grassland (steppe) which spans

almost the entire continent. The main area of temperate forests is in East Asia, with deciduous and mixed forests in the north, rich evergreen "laurel" forests in the south, and extensive areas of mostly secondary pine forests throughout. Mountain areas of Asia have many endemic species, especially relict conifers, and the mountains of East Asia represent the only truly large mountainous area in the warm-temperate and humid subtropical zones of either hemisphere. Northern Asia was less glaciated than Europe or North America and contains enormous expanses of relatively diverse Siberian conifer forests, polar and upland tundra, and Lake Baikal (the world's deepest). Wetlands in Asia include mangroves, coastal strand forests, salt marshes and estuaries, and terrestrial swamp forests, marshes, and bogs, most of which are highly productive and represent critical habitat for terrestrial as well as aquatic

animals. Despite long histories of human habitation and landscape alteration, Asia retains the highest biodiversity of any continent, due not only to its size but also to its climatic and topographic complexity and its complex geological and evolutionary history. This biodiversity is threatened in Asia as elsewhere by human overpopulation and overdevelopment.

Asia the Region

Asia is traditionally separated from Europe, with which it shares the world's single largest land-mass, Eurasia (**Figure 1**). Even by this cultural definition, however, Asia remains the world's largest continent and extends almost halfway around the world, from a small western coastline on the

Mediterranean Sea (about 25° E in Turkey) eastward to the Bering Strait (170° W) separating it from Alaska. Asia also spans almost the entire latitudinal range of the Northern Hemisphere, from a northern coastline in the Arctic zone to islands lying slightly south of the equator in Indonesia. Asian superlatives include the world's

- highest mountain (Mt. Everest, 8848 m) and mountain range (Himalaya);
- largest highland plateau (Tibet);
- lowest terrestrial elevation (Dead Sea, −400 m);
- largest (Caspian Sea, 143,200 km²) and deepest (Lake Baikal, 1620 m) lakes; and
- coldest, most continental region except for Antarctica (northeastern Siberia), with mean monthly temperature ranging from 20 to −60 °C and extremes to −80 °C.

Figure 1 Location and main physiographic features of Asia. Asia extends almost halfway around the world, from Turkey and Arabia in the west to the Bering Strait in the east. It also extends from the Arctic Ocean in the north to slightly south of the equator in Indonesia. Middle Asia extends across the Turanian Basin from the Caspian Sea to the Tien-Shan and Altai mountains and is largely steppe and desert. Central Asia includes the high, cold Tibetan Plateau and the desert basins to its north, on into the steppes of Mongolia. Siberia (Asiatic Russia) is the mostly forested region north of the east–west mountains and Middle Asian deserts. Other regions and the geological development of Asia are described in the text.

Also found in Asia are

- the world's third (Borneo) and fifth (Sumatra) largest islands;
- four of the world's seven rivers over 5000 km long (Yangtze, Ob'-Irtysh, Yenisey-Angara, and Huang-He);
- one of the world's three regions with essentially no rainfall (Tarim Basin); and
- two of the world's three stations with more than 10 m of average annual rainfall (windward slopes of easternmost India at Cherrapunji and Yakushima Island of Japan).

In addition, Asia has been home to some of the oldest human cultures and to areas of very long, continuous human habitation, especially in the Middle East, India, and Southeast and East Asia.

Asia represents the largest part of Laurasia, the northern half of the supercontinent Pangaea, which existed in the late Paleozoic and broke up during the Mesozoic (Table 1; Raven and Axelrod, 1974). Eurasia began to separate from North

America around 180 million years ago, but contact was reestablished in the Cretaceous when Siberia approached Alaska, forming Beringia. At about this time, southwestern Asia also began to be influenced by northward-moving Africa, a portion of Gondwana, the southern part of Pangaea.

The present-day geologic and physiographic structure of Asia, however, is dominated by the Himalayan Mountains and Tibetan Plateau, which arose when India, another piece of former Gondwana, collided with Asia in the Eocene. In addition to the Himalaya, a mountain node was created at its western end, from which other major mountain ranges radiate in various directions. The most important of these is the Tien Shan-Altai system, which extends to the north-northeast into Mongolia, dividing interior temperate Asia into

- a western part, called Middle Asia in Russian literature (essentially Turkestan and the Turanian Basin), influenced far inland by westerly winds from the Mediterranean; and

Table 1 Some major events in Asia's geological and evolutionary history^a

		<i>Geological and climatic events</i>	<i>Biotic events</i>
Paleozoic Era (> 225 million BP)			
Silurian	425–400 m	Climate similar to present?	First vascular and land plants
Carboniferous	345–280 m	Warm and humid	Forests of ferns, horsetails, etc.
Permian	from 280 m	Pangaea; glaciation at S pole	First ginkgos and mosses
Mesozoic Era (225–65 million BP)			
Triassic	225–185 m BP	Breakup of Pangaea begins; climate cool and humid	Ginkgos and cycads dominant
Jurassic	185–135 m	Breakup of Pangaea: W. Gondwana	Conifers and cycads dominant
Cretaceous	135–65 m	"Greenhouse" climate, high sea level	Angiosperms dominant
		Major separations	
		Gondwana (130–100 m BP)	
		Eurasia and N. America (180 m, initially)	Modern plant orders exist; some modern families and genera exist
		Europe and N. America (80 m; not north)	
		Major contacts	
		SW Asia and Africa (100? m)	
		Siberia and Alaska (70 m)	
Tertiary Period (of Cenozoic Era)			
Paleocene	65 m BP	Africa and Europe separate temporarily	
Eocene	60–38 m	Final separation of Europe and N America; Beringia becomes warmer	Most modern families, many genera exist
		Himalaya and central Asia plateaus form as India collides with Asia	Madro-Tertiary geoflora First primates
Oligocene	38–26 m	Alpine orogeny stresses Middle Asian mountains	
Miocene	26–7 m	Australia approaches SE Asia; islands form Global climates become cooler and drier	
Pliocene	7–2 m	Arabia splits from Africa and contacts Asia, forcing Turkey westward	Most modern plant taxa; herbaceous plants abundant
Quaternary Period (of Cenozoic Era)			
Pleistocene	2–0.01 m BP	Glacial and interglacial periods;	N–S migration of vegetation zones, with loss of taxa unable to cross barriers
	18 k	N Europe glaciated, Siberia less	
	14–12 k	Last glacial maximum: sea 150 m lower, land bridges and wider coastal plains	Tropical areas drier
		Warming and glacial retreat	
Holocene	from 10 k	Continued warming	Temperate and high-latitude soils and biomes redevelop
	8–5 k	Hypsithermal period (warmest)	
	5 k	Sea reaches present level; cooling	Paludification in Siberia

^aTimes are in millions (m) or thousands (k) of years before present (BP).

Sources: Pearson (1995); Bridges (1990), and Raven PH and Axelrod DI (1974) Angiosperm biogeography and past continental movements. *Ann. Missouri Bot. Garden* 61: 539–673.

- an eastern part, called Central Asia (essentially the Tibetan Plateau and northwestern China, plus Mongolia) dominated by the Asian monsoon system.

Other radial ranges from the central node include the Hindu Kush mountains to the southwest, which separate Afghanistan from Pakistan; the Paropamisus and Kopet Dagh further west, which separate Afghanistan and Iran to the south from Turkistan to the north; and the Kunlun and Karakoram ranges, which run east–west across the Tibetan Plateau. South of Tibet, of course, lies the Deccan Plateau of peninsular India, with its Eastern and higher Western Ghats ranges. Southeast of Tibet, the Yunnan-Guizhou Plateau (southwestern China) represents an upland transition to still mountainous Southeast Asia, with its Dawna and Arakan ranges (Burma) and Annamese cordillera.

In southwestern Asia, the Iranian Plateau (extending into Afghanistan), the Anatolian Plateau of central Turkey, and the Arabian Plateau (peninsula) have all been affected to some extent by the interaction between Africa and Asia. More linear mountain ranges in Asia include the Urals, the Hinggan-Ling and Changbai-Shan in northeastern China, and the Sikhote Alin, Kamchatkan, and other ranges of eastern Siberia. Major interior basins include the Turanian Basin east of the Caspian Sea, the West Siberian Lowland (the world's largest marshland), and the Tarim Basin of Central Asia. Other lowlands include the densely populated East China Plain and many river valleys of Asia: Ganga, Indus, Tigris–Euphrates, Brahmaputra, Irrawaddy, Yangtze, and Huang-He. Less populated lowlands extend along the Siberian coast (with the Taimyr peninsula) and the valleys of the Amur and north-flowing Lena, Yenisey-Angara, and Ob'-Irtysh rivers. The remaining

structure of Asia is provided by the volcanic arcs forming the Kuril, Japanese, Okinawan, Philippine, and Indonesian archipelagos, along with continental islands such as Sri Lanka, Hainan, Taiwan, and the smaller Siberian Arctic islands and Andaman-Nicobar chain. All of these areas represent regions of localized environmental conditions and ecosystems, with more or less individual characteristics and diversity.

Climatic zonation in general and major regions in Asia are summarized in **Table 2**. The single most important climatic feature of Asia is the monsoon system, which affects an area from Japan and northeastern China in the east, through China and Southeast Asia, to India and Sri Lanka in the south. The cooling of the vast mid-latitude land-mass in the autumn and winter produces a very large, stable center of high atmospheric pressure over Mongolia and northern China, which feeds cold, dry air outward over the rest of East, Southeast, and South Asia throughout the winter. As a result, and aided perhaps by the many east–west mountain ranges, mean winter temperatures are generally low but extremes are not far below the means. In summer, continental warming causes rising air, which draws wet air masses in off the adjacent Pacific and Indian Oceans, greatly accentuating the rainier season which, due to global atmospheric circulation, would occur in summer over most of this area anyway. The “summer monsoon” arrives as two almost stationary rain fronts which, over the course of about one month, penetrate from Kerala across the rest of India and from Japan across Korea into eastern China. Although the monsoon quickly brings warm rains to south Asia, it brings a cooler, mistier rainy season as it crosses Japan into Korea and China. The cold, dry winter is much more reliable than the summer rains. Heavy winter snow can delay the warming of the

Table 2 Global climatic zonation in lowlands, with regions in asia

<i>Zone</i>	<i>Temperature extremes</i>	<i>Significance</i>	<i>Asian examples</i>
Tropical	No frost or other “cold” temperatures ever	Sensitivity of many tropical plants to non-freezing cold	South Asia and East Indies
Subtropical	Occasional frost or near frost, not every year and not below about -1°C	Frost sensitivity of tropical evergreen and most other tropical plants	Southern China, Taiwan, south Asian foothills, northern Arabian Peninsula
Warm-temperate	Light to moderate frost, every year or nearly so; absolute minima not $< -15^{\circ}\text{C}$	Annually leaf-changing broad-leaved evergreens tolerate, (sub)tropical evergreens may not	Eastern, inland SE and SW China, southern Japan; Mediterranean region
Temperate	Significant frost every year; occasional temperatures below about -15°C	Coldness tolerance limit for evergreen broad-leaved plants (e.g., internal ice formation)	Northern China and Japan, Korea, interior Asia from Mongolia to Turkey
Cool-temperate	Moderate to significant frost every year, plus cool summer; minima can be $> -15^{\circ}\text{C}$ if oceanic	Growing-season warmth marginal for many typical temperate plants, including deciduous	Hokkaido (minima $< -15^{\circ}\text{C}$)
Boreal	Cool, short summer and long severe winter; absolute minima $< -15^{\circ}\text{C}$, perhaps $< -40^{\circ}\text{C}$	Growing season insufficient for most deciduous trees (exceptions: larch, birch, etc.)	Most of Siberia, northern Manchuria
Polar	Short summers below 10°C and long severe winters below 0°C ; extremes $< -40^{\circ}\text{C}$ unless oceanic	Growing season too cold for wood-producing enzymes; no trees or large shrubs	North-coastal Siberia, islands of Arctic Ocean

landmass to such an extent that the summer monsoon “fails” in places such as India, with disastrous effects on crops.

The Philippines and East Indies are less affected by the monsoon and more by the seasonal shift in global circulation. Near the equator, warm perhumid conditions continue throughout most of the year, with only a short dry season if any at all. The length and degree of the dry season increase away from the equator, reaching several months in the northern Philippines but also in some eastern parts of Indonesia (Lesser Sunda Islands as well as eastern Java and southernmost Borneo and Sulawesi).

Southwestern Asia is not affected by the monsoon but rather by the pervasive effect of the subtropical high-pressure belt. This belt of descending dry air migrates north–south seasonally, creating “Mediterranean” climates with dry summers in Turkey and throughout the Mediterranean borderlands. To the south, however, subtropical high pressure remains the dominant influence throughout the year, causing the desert belt across North Africa, the Arabian Peninsula, and as far east as the Thar desert in Pakistan and western India.

Northern Asia (Siberia) is dominated by its high latitude and large land area, resulting in ultracontinental climates with short summers and long severe winters rivaling the northern polar region in degree of cold.

Biodiversity

Angiosperms are thought to have originated in South–east Asia, and indeed Asia is thought to contain many other foci of more recent biotic radiation as well. During the Pleistocene, when many species were lost from heavily glaciated Europe and North America, glaciation in Asia was less extensive, especially in the east. The Scandinavian ice sheet extended east to the Urals, but Siberia remained largely ice-free except in the northwest and in the mountainous northeast. A large Pleistocene refuge for temperate Asian plants was also readily available in southern China. These climatic (and related sea-level) changes, plus the physiographic complexity of Asia, all contributed to the development and maintenance of high biotic diversity in Asia, both in and within genera. Among vascular plants, for example, both Siberia and temperate east Asia generally show higher diversity than comparable latitudes in Europe and North America.

The most complete compilation of recent estimates of both species richness and the protection status of taxa and ecosystems is titled *Global Biodiversity* (Groombridge, 1992), from which summaries will appear throughout this article. Species richness and endemism of plants in the different countries and regions of Asia are summarized in Table 3. China and Malesia are thought to have about 30,000 plant species each (most not in common), India may have 15,000 species, and tropical and subtropical Asia may have a total of at least 50,000 species. By comparison, Latin America may have as many as 85,000 species, but this includes the region from Mexico to temperate southern South America. Within Asia, China has the largest number of plant species at 30,000, followed by Indonesia (20,000), India (15,000), Malaysia (12,000) and Thailand (12,000). A special feature of East Asia is its large number of endemic plant families, many of which

are mono-specific, as shown in Table 4. Species richness is lowest in the dry areas of the Arabian Peninsula and mainland southwestern Asia, but rates of endemism are high in some of these drier areas. Inventories are incomplete in all areas, with only small Brunei claiming more than 20% completion. No inventory statistics at all were available for Southeast Asia, except for Thailand and Myanmar.

Estimates of species richness and endemism in four major groups of animals, but without indication of inventory status, are provided in Table 5 (from Groombridge, 1992). Species richness is generally lowest in the drier areas, but the number of reptiles is still high. Numbers of birds are also fairly high in mainland southwestern Asia. Other sources of biodiversity data include the United Nations Environment Programme *Global Biodiversity Assessment* (Heywood, 1995) and the various publications of the World Resources Institute.

Regionalization and Biomes of Asia

Global regionalization of climatic types, as related to causal mechanisms (latitude and global circulation) and natural ecosystems, has been portrayed perhaps best by the widely used global system of Heinrich Walter (1985). This and the major large-area landscape types, called biomes (e.g., tropical rain forest and temperate grassland), provide a geographic framework for regionalizing the ecosystems of Asia. An attempt is made in Table 6 to juxtapose the main biome types, the climate type in which they occur, the corresponding Bailey ecoregion class, and the corresponding International Union for the Conservation of Nature biogeographic provinces in Asia. Note that the “Savanna” ecoregion also includes the region of tropical moist and dry deciduous forests (“monsoon forests”) that stretches across South and Southeast Asia and which corresponds to the larger tropical wet–dry climatic regions of Africa and South America, with their areas of tropical deciduous forest, woodland, and savanna. Tropical deciduous forests are not recognized in some newer classifications because they have been so completely converted into savanna. Areas of tropical deciduous forest still remain in Asia, however, especially in the Ghats Mountains of India and from the Deccan Plateau to interior Southeast Asia. Note also that one must be careful with Russian and Chinese terminologies which use terms such as “Hot/Warm Continental” and “subtropical” for temperate forest regions which have cold to severely cold winters.

Using the synthesis presented in Table 6, Asia can be divided into four main regions of bioclimate and associated ecosystems:

1. Tropical Asia, including the tropical rain forest and monsoon forest regions, the tropical islands, and the various elevational belts of tropical mountains
2. the dry region of subtropical southwestern and interior Middle and Central Asia, including the subtropical and interior deserts, the temperate grasslands, the Mediterranean-type ecosystems in the southwest, and the drier mountain ranges
3. East Asia, the monsoonal but extra-tropical region of subtropical and warm-temperate evergreen broad-leaved forests (“laurel forests”) and of temperate deciduous forests,

^aCompiled by the World Conservation Monitoring Centre (WCMC). The last two columns refer to the date and status of country inventories, using codes from the original source.

^bPercentage endemism is calculated from the data, unless in square brackets.

^cDate is the date of the information provided to the WCMC.

^dStatus includes percentage completion (first number) and method (counted/estimated): 1, <5%; 2, 5–10%; 3, 10–15%; 4, 15–20%; 5, >20%; c, counted; el, approximate count; e2, extrapolation; e3, estimated based on any available information and comparable floras.

^eData for North and South Korea are combined; no data are available for combined Yemen.

Source: The data are regrouped by region from those presented in the Global Biodiversity report (Groombridge, 1992, p. 80).

Table 4 Endemic families of east Asia^a

Polygeneric families	
Helwingiaceae	(4–5/4–6)
Carlemanniaceae	(2/4, E. Himalaya, Assam, N. Myanmar, N. Indo-China to Yunnan; 1 disjunct in Sumatra)
Podoaceae	(2/3, central Yunnan to E. Himalaya and N. Thailand)
Monogeneric families	
Hostaceae	(10–40)
Stachyuraceae	(10)
Cephalotaxaceae	(9)
Aucubaceae	(7–11, to E. Himalaya and N. Myanmar, 1 to Russian Far East)
Toricelliaceae	(2, E. Himalaya, N. Myanmar to central China)
Triplostegiaceae	(2 1 disjunct in Sulawesi and New Guinea)
Euptelaceae	(2)
Trapellaceae	(1–2, extending to Russian Far East)
Monospecific families	
Nandiniaceae	
Circaeasteraceae	(not Japan, excluding <i>Kingdonia</i>)
Tetracentraceae	(not Japan)
Cercidiphyllaceae	(not Himalaya)
Euryalaceae	(not Himalaya but to India and Bangladesh)
Plagiopteraceae	(disjunct in India, Bangladesh, lower Myanmar, Thailand, Guangxi)
Pottingeriaceae	(Assam, N. Myanmar, NW Thailand to Yunnan)
Trochodendraceae	(not mainland China)
Bretschneideraceae	(China to N. Laos and N. Thailand)
Dipentodontaceae	(central China to NE India, Himalaya)
Sargentodoxaceae	(only China to N. Vietnam and N. Laos)
Rhoiptelaceae	(only SW China to N. Vietnam)
Sladentiaceae	(only SW China and adjacent Myanmar, Thailand)
Acanthochlamydeaceae	(only in Hengduan mtn. to E. Tibet)
Davidiaceae	(only in China)
Ginkgoaceae	(only in China)
Eucommiaceae	(only mainland China)
Glaucidiaceae	(only in Japan)
Pteridophyllaceae	(only in Japan)
Sciadopityaceae	(only in Japan)

^aNumbers in parentheses represent number of genera followed by number of species or number of species only (if monogeneric).

with the more humid uplands and mountain ranges in these areas

4. Boreal and polar Asia, including the boreal forests of Siberia, northeasternmost China, and northern Mongolia and the tundra landscapes across the northern Siberian coastal plain and in the mountain areas of eastern Siberia.

Treatment of the various ecosystems of Asia will follow this framework, with an emphasis on vegetation since it provides the basic physical and trophic structure of ecosystems. Wetlands, coastal ecosystems, and some artificial ecosystems will be treated separately.

Estimates of vegetation cover type, percentage cover, and carbon storage, by country and region, are summarized in **Table 7** (Groombridge, 1992). The most extensive forest cover

is in eastern to southern Asia and in Siberia, with non-forest landscapes dominating southwestern Asia. These data probably overestimate the extent of remaining forest.

Allotted space does not permit a detailed description of regional vegetation composition or even a more complete bibliography. Some general treatments, from which one can find references to more regional descriptions, include the following:

Global: Archibold (1995) and Walter (1985)

Tropical: Champion and Seth (1968), Mani (1974), and Whitmore (1984)

Dry region: Walter and Box (1983) and Zohary (1973)

East Asia: Missouri Botanical Garden (1983), Numata (1974), and Wang (1961)

Boreal/polar: Walter (1974)

Mountains: Chen *et al.* (1986), Troll (1972), and Walter (1974).

For animals, one might start with the extraordinary syntheses of Schaller (1998).

Tropical Asia

Tropical Asia is the region of mainly low-lying topography and warm, at least seasonally humid climates which extends from India to the Philippines and East Indies (i.e., excluding all of dry southwestern Asia). Much of the region is coastal lowland, and the highest point is on an island, at Mount Kinabalu (4110 m) in northern Borneo. The region can be divided climatically into two main zones:

1. The perhumid equatorial zone, covering most of the East Indies and southern Philippines, the Malay Peninsula, and extending along the windward southwest-facing coastlines of mainland southern Asia to southern Kerala and Sri Lanka.
2. The seasonally wet–dry zone to the north, mainly across interior southern Asia from India to Vietnam and the northern Philippines, but also including the eastern Sunda Islands (6–11° S) and some other island areas, including rain shadows such as eastern and northern Sri Lanka.

The natural biome of the equatorial zone is tropical rain forest and other humid tropical evergreen forests, whereas the wet–dry zone contains natural landscapes ranging from moist and dry deciduous forests to savanna and small areas of dry evergreen forest mainly in Thailand. Other ecosystems, such as swamp forests, kerang (sclerophyll scrub), and viny limestone forests, occur on particular substrates. These main characteristic vegetation types of tropical Asia and their topographic or substrate affinities are summarized in **Table 8**. Characteristic vegetation belts in mountains are summarized in **Table 9** (Whitmore, 1984).

Humid Tropical Forest

Tropical rain forest is tall, multi-layered, evergreen broad-leaved forest characterized by many epiphytes, climbing plants, and a tremendous richness of tree species with dark green, thin-coriaceous leaves, many with attenuated “drip tips” for better drainage but otherwise all looking very similar. The air is constantly humid, but the canopy is exposed each day to high solar radiation, resulting in a drier canopy microclimate and a more perhumid microclimate in the forest understory. Many tree

species respond to this difference with somewhat smaller, thicker canopy leaves and larger, thinner (and often darker) understory leaves, all on the same tree. In true tropical rain forest, the only seasonality is the difference between day and night. As a result, the main phenological functions of the trees tend to occur simultaneously. A given tree may be seen to be flowering, flushing new leaves, dropping individual or small bunches of old leaves, and carrying ripening or ripe fruit simultaneously on different branches.

As one proceeds away from the equator, subtle climatic cues begin to appear: seasonal periods of less precipitation and slight seasonal temperature variations. The result is a “tropical seasonal evergreen forest” which is still tall and very diverse but in which phenological functions become synchronized and more sensitive) plant types become somewhat less abundant, such as epiphytes with only aerial roots. Further from the equator, as the tropical dry season begins to become more pronounced, the forest becomes a “tropical

semi-evergreen forest" containing some deciduous trees and still fewer epiphytes (Walter, 1985). In most tropical trees, deciduousness appears to be a facultative characteristic. This is demonstrated by two facts:

1. Many tropical tree species are evergreen in one part of their range but lose their leaves in a drier part.

2. Many individual tropical trees have been observed to keep almost all their leaves in wetter years and lose most or all of their leaves in drier years.

Temperate tree species, on the other hand, often die within a few years if planted in the tropics, apparently due to lack of the seasonal cues necessary for vernalization.

^aBiome regions are denoted by names commonly used in regional and global treatments of terrestrial vegetation and biomes (Reproduced from Archibald OW (1995) *Ecology of World Vegetation*. London: Chapman & Hall, and Walter (1985) *Vegetation of the Earth and Ecological Systems of the Geobiosphere*, 3rd ed. New York: Springer-Verlag, and the "Ecosystems of the World" book series).

^bClimate types are those of Walter (1985): I, equatorial; II, tropical summer-rain; III, subtropical arid; IV, mediterranean; Ve, warm-temperate (humid east sides); Vm, marine west-coast (perhumid); VI, typical temperate (humid) VII, temperate continental (subhumid); VIIa, temperate arid; VIII, boreal; IX, polar; X, highlands (unclassified).

^cEcoregions are from Bailey RG (1996) *Ecosystem Geography*. New York: Springer. See also the world map from 1989.

^dBiogeographic provinces are from the classification by Udvardy MDF (1975) IUCN Occasional Paper No.18. Morges, Switzerland: International Union for the Conservation of Nature and Natural Resources.

Tropical rain forest has its largest extent in Asia from peninsular Malaysia through the East Indies and southern Philippines. It can also be found, however, along the mainland coast from peninsular Thailand and Myanmar to Bangladesh, in Kerala and southwestern Sri Lanka, and northward through the mountains of Southeast Asia, Myanmar, and Assam to southernmost China (Yunnan) and the foothills of the eastern Himalaya (Whitmore, 1984). In these more northerly areas, extending beyond the Tropic of Cancer, the rain forest takes on a more subtropical character but maintains high diversity and its multi-layered structure, with abundant epiphytes and lianas.

Tropical rain forest in general is composed of many tree species from families such as the Lauraceae, Rubiaceae, Moraceae, Meliaceae, and Leguminosae, the latter two usually with compound leaves and somewhat smaller leaflets than the typical rain forest leaf. Tropical rain forest reaches its greatest species richness in Southeast Asia, but here another family, the Dipterocarpaceae, provides more of the rain forest species than does any other family elsewhere. Some of the most important tree genera in Malaysia, Indonesia, and adjacent mainland areas include *Dipterocarpus*, *Shorea*, *Hopea*, *Dryobalanops*, and *Vatica* (Dipterocarpaceae); *Mitragyna* and other Rubiaceae; trees with large buttress roots such as *Heritiera* (Sterculiaceae); *Aglaia* and *Dysoxylum* (Meliaceae); *Mangifera* and other anacards; *Ficus* and *Artocarpus* (Moraceae); other trees with large edible fruits such as *Durio* (Bombacaceae); *Koompassia* and other legumes; and other families such as Dilleniaceae, Flacourtiaceae, and Thymeliaceae. Most genera are mainly tropical. The higher understories contain trees of the same physiognomy but also various palms (e.g., *Licuala*), even climbing palms (rattans), and other climbers such as stranglers (especially *Ficus* spp.). The ground layer is largely composed of frutescent but entirely herbaceous monocots such as *Heliconia* and *Alpinia* (both Zingiberidae). Tall bamboos, of genera such as *Calamus* and *Phyllostachys*, may form colonial stands where the forest has been disturbed frequently and opened, especially in mountains. Secondary vegetation may also involve larger-leaved, deciduous, fast-growing

arborescents from the characteristic pioneer genera *Macaranga* and *Mallotus* (analogous to *Cecropia* in the tropical Americas). Some other characteristic secondary genera include *Melastoma*, *Glochidion* (Euphorbiaceae), and *Trema* (Ulmaceae).

Birds, amphibians such as tree frogs, reptiles such as tree-dwelling lizards, and countless insects are the main groups of animals in tropical rain forests. Mammals are less numerous but include both larger ground-dwellers such as rodents and flying mammals (i.e., bats). Most animals are probably insectivorous, although many are also mixed feeders, including various mammals which range between the canopy and the ground. Some larger ground animals are herbivores, eating mainly plant roots and fallen fruit. Ants are an especially interesting and important group for their role in dispersing plant diaspores and in decomposition and nutrient cycling.

Monsoon Forest (Moist Deciduous Forest)

Monsoon forest is not always a well-defined term but is used most commonly for the tall tropical "moist deciduous forest" with fairly large, soft (malacophyllous) deciduous leaves which occurs in areas with essentially perhumid rain forest conditions during a wet season which is longer than the dry season. Since the "rain-green" leaves wilt when soil water is depleted (about a month after the end of the rainy season), there are generally no bright colors in the tropical "autumn" (with the exception of *Excoecaria agallocha* in mangroves). In the tropical "spring," however, many trees bloom brightly in the month before the rainy season, cued by increasing temperatures, and the new leaves of many species are also bright reddish before enlarging and receiving their full dose of chlorophyll. Moist deciduous forest is not as species-rich as the rain forest but may still reach canopy heights of 30 m and have more species than temperate forests.

Moist deciduous forest occurs in the Western Ghats (Kerala) and in those parts of lowland and mountainous eastern India, Myanmar, and Southeast Asia which have relatively short dry seasons (Champion and Seth, 1968). In the Western

Table 8 Tropical humid forest types of southeastern Asia

Climate	Soil water	Zone	Elevation	Soil type	Forest type
Everwet	Dry land	Inland	Lowland (<1200 m)	Zonal	Lowland rain forest
			Mountains		
			1200–1500 m		Lower montane rain forest
			1500–3000 m		Upper montane rain forest
			3000 m to treeline		Subalpine forest
	Near surface	Coastal	Lowland (mostly)	Podzolized sands	Heath forest
				Limestone	Limestone forest
				Ultrabasic rock	Forest on ultrabasic rock
				Sand	Beach vegetation
					Mangrove forest
Wet–dry	Moderate dry season Increasing seasonal deficit	Inland	Wet permanently Wet periodically	Oligotrophic peat	Peat swamp forest
				Eutrophic (muck and mineral)	Freshwater swamp forest
					Seasonal swamp forest
					Semievergreen forest
					Moist deciduous forest
					Dry deciduous forest

Table 9 Generalized vegetation belts in mountains of tropical southeastern Asia

Belt	Elevation (m)	Floristic zone	Main taxa
Upper montane	1500–2100	Montane ericaceous	Ericaceae, Myrtaceae, conifers
Lower montane	1200–1500	Oak-laurel	Fagaceae, Lauraceae
	750–1200	Upper dipterocarp	<i>Shorea</i> , <i>Dipterocarpus</i>
Lowland	300–750	Hill dipterocarp	Lowland + <i>Shorea curtisii</i>
	0–300	Lowland dipterocarp	Many dipterocarps, especially <i>Dipterocarpus</i> , <i>Shorea</i> , <i>Dryobalanops aromatica</i>

Source: Modified from Symington (1943). The oak-laurel zone corresponds closely to subtropical/warm-temperate laurel forests further north (Ohsawa, 1995).

Ghats, one of the most important trees is teak (*Tectona grandis*), which grows very straight but has unusually large, soft leaves very subject to insect herbivory. Other important trees include *Shorea* spp., *Terminalia tomentosa*, *Lagerstroemia lanceolata*, *Grewia tiliaefolia*, and *Pterocarpus marsupium*. To the east one encounters sal (*Shorea robusta*), a dipterocarp and another of the most important forest trees of tropical Asia, economically and ecologically. Moist deciduous forests with *Shorea* continue eastward from the Eastern Ghats through Assam and Myanmar into parts of Southeast Asia. The composition and biogeography of the moist as well as dry deciduous forests of India are well described by Mani (1974), who provides photographs of various forest areas which are now probably gone. Other moist deciduous forests occur in scattered mountain areas of Sri Lanka and the East Indies but have been largely destroyed over most of their area.

Tropical Dry Forest, Scrub, and Savanna

“Dry deciduous forest” occurs where the dry season is at least as long as the wet season and involves shorter, somewhat more open forests dominated by trees with usually smaller leaves, including many Leguminosae. Species richness and leaf area are lower than in monsoon forest or rain forest, and canopy height is usually not more than about 15 m. In still

drier areas, dry forest may grade into dense but shorter thorn-scrub, dominated by sprawling, thorny arborescents with sparse foliage of quite small leaves (or leaflets), many of which may be Leguminosae. In other drier areas, especially on relatively flat terrain, trees may be only widely scattered in savannas dominated by tall to short seasonal grasses. In most areas, all three of these vegetation structures may be interspersed in mosaic landscapes, with forest now usually replaced by more extensive areas of degradation stages: thorn-scrub, sclerophyll scrub, and derived savanna. This kind of rain-green mosaic landscape occurs over much of the Deccan Plateau and Ganga Valley, in the “dry belt” of interior Myanmar, and in much of interior Southeast Asia. It also occurs on the drier northern to eastern side of Sri Lanka and in drier parts of the northern Philippines and the East Indies, especially in the Lesser Sunda Islands of eastern Indonesia. An interesting variant of this rain-green response to the tropical dry season is represented by the somewhat open “dry evergreen forest” of interior Thailand.

The gradual transition between moist and dry deciduous forest occurs in particular across the Deccan Plateau, from moist deciduous forest in the Western Ghats to thorn-scrub and savanna in the rain shadow immediately eastward and to dry deciduous forest, and again to moist deciduous forest further eastward. Teak and sal still occur in the dry forest, but trees such as *Diospyros melanoxylon* (ebony), *Anogeissus latifolia*

(Combretaceae), leguminous taxa such as *Acacia* (especially *A. catechu*) and *Cassia*, and low arborescents such as *Zizyphus* become more important. This is also the home of the evergreen but semi-parasitic sandalwood tree (*Santalum album*). Further east, in interior Southeast Asia, the main type of dry deciduous forest is “dry dipterocarp forest,” reaching over 20 m in height and with canopy species such as *Dipterocarpus tuberculatus*, *D. intricatus*, *Shorea obtusa*, and *Sh. siamensis*. In addition, dry evergreen forest dominated by evergreen dipterocarps such as *Hopea ferrea* and *Shorea henryana* covers significant areas, especially in Thailand.

Humid Tropical and Subtropical Mountains

The main truly tropical or subtropical humid mountain areas in Asia are the lower slopes of the Himalaya (south side), the Western and Eastern Ghats in peninsular India, the mountains of Southeast Asia, and the smaller ranges and isolated volcanic peaks of the East Indies, the Philippines, and Sri Lanka. A general zonation scheme for the vegetation of mountains in tropical Asia was shown in Table 9. As one ascends any mountain range, two climatic changes occur which together quickly reduce the effect of any dry season which may exist in the lowlands:

1. Temperature decreases (approximately 6 °C per kilometer), reducing potential water loss to evapo-transpiration.
2. Humidity and precipitation increase, at least up to the quasi-permanent cloud belt, which is usually 1000–1500 m above the base of the mountains (lower in more humid areas).

Thus, a tropical dry season in the surrounding lowland may disappear completely with a climb of 1000 m or less. At some elevation, generally between 800 and 1200 m, the lowland forest is replaced by a belt of tropical montane forest reminiscent of the evergreen laurel forest of the warm-temperate zone and dominated by temperate taxa such as Ericaceae and Ilex, plus subtropical taxa such as Myrsinaceae, Symplocaceae, Rubiaceae, and understory Lauraceae and Theaceae. From the lowland forest to this montane forest, leaf size typically changes from normal mesophyll to a mix of smaller notophyll and microphyll (Ohsawa, 1995). Above this there may be a low, dense, distinctly microphyll cloud forest of laurophyll treelets covered by mosses and other epiphytes. Of the truly tropical Asian mountains (i.e., excluding the upper parts of the Himalaya), however, only Mt. Kinabalu is high enough for an alpine belt and it is only rock (old volcanic plug) at its top.

Mount Kinabalu (4110 m, northern Borneo) is the highest mountain between the Himalaya and New Guinea (geologically part of Australia). Due to its location near the equator, Mt. Kinabalu contains taxa from both hemispheres, including some distinctly Australian elements such as *Leptospermum* and *Platyclusus*. Due to the discontinuous nature of the Southeast Asian land-mass and its fluctuating biogeographic history, Mt. Kinabalu also represents a true biogeographic “island in the sky” and one of the most interesting goals of any knowledgeable geobotanist. The lower slopes are covered by lowland and montane (subtropical) rain forest, followed by laurel forest rich in *Syzygium* and other amphi-tropical taxa. Near the probably edaphic treeline (around 3500 m), on shallow soil,

is a belt of low, open forest dominated by *Leptospermum*, with extremely small (leptophyll) leaves reminiscent of Australian forms and the *Kunzea* woodlands of New Zealand. Other interesting features include 30-cm-wide, brown, foul-smelling, fly-pollinated flowers of *Rafflesia* and the diversity of *Nepenthes* species, with their insectivorous pitchers hanging on vines.

The mountains of mainland Southeast Asia are less described but generally show the same vertical zonation as described elsewhere (Whitmore, 1984). Evergreen *Castanopsis*, *Lithocarpus*, and *Cyclobalanopsis* (evergreen *Quercus*), dominants in the laurel forests of East Asia, extend far into the tropics in Southeast Asia to form extensive montane forests. Satellite data have suggested that some relatively large areas of montane rain forest and laurel forest may remain.

In the Western Ghats of Kerala, moist deciduous forest forms a lower montane forest belt, followed upward by semi-evergreen transition and then evergreen laurophyll cloud forest. The same zonation probably occurred on other mountains of southern India and Sri Lanka but has been largely destroyed, converted especially for tea plantations. A similar zonation occurs on the lower southern slopes of the eastern Himalaya but involves more subtropical species.

Dry Regions of West and Interior Asia

The dry regions of Asia include the subtropical deserts of southwestern Asia, the adjacent region of Mediterranean-type ecosystems from Turkey to Israel, the Asian portion of the temperate grassland corridor from the Ukraine to Mongolia and northern China, and the semi-desert and desert regions of both Middle Asia (Turkistan) and Central Asia (Gobi and northwest China as well as the high, dry Tibetan Plateau). Major mountain ranges separate some of these and adjacent regions, especially the Himalaya, which blocks moist monsoonal air from the south, and the Tien Shan system, which blocks moist air from the Mediterranean and thus separates summer-dry Middle Asia from summer-rain Central Asia. Most of these dry climates are also continental, reaching coastal areas only in the Middle East. The Mediterranean region contains landscapes ranging from small areas of sclerophyll forest and montane conifer forest to sclerophyll shrublands and dwarf-scrub. The temperate grasslands range from tall-grass prairies and meadow-steppes in the north to drier, open steppes in the south, following the north–south moisture gradient which obtains across most of the continent. These steppes eventually grade southward into the temperate semi-deserts and deserts.

Subtropical Deserts

Deserts (*sensu strictu*) have essentially no vegetation, whereas semi-deserts have scattered plants. The subtropical arid zone of Asia contains large areas of extreme desert: the Rub al-Khali (empty quarter) of the southeastern Arabian Peninsula, some areas of the Syrian desert (in Iraq and northern Arabia, not Syria), and the Dasht-e-Kavir and smaller areas of interior Iran. The rest of the subtropical desert area, from the Middle East to westernmost India, is mostly semi-desert, with widely scattered xeromorphic dwarf-shrubs, desert grasses, and

ephemeral herbs on coarse, often gravelly or even rubbly substrates.

Desert conditions may have existed since the earlier Paleozoic. Whether the desert flora arose this early, or in the Miocene (expanding during the colder, drier Pliocene and Pleistocene), the desert flora of Asia has probably been closely related to that of northern Africa for a long time. Although total species richness is low and perhaps because there are essentially no true native stem-succulents, the vegetation of the Middle Eastern deserts shows a wide variety of adaptations of form and seasonality to avoid dehydration (Walter, 1985; Zohary, 1973). Some dwarf-shrubs are evergreen but greatly reduce their leaf area at the beginning of the dry season (e.g., *Artemisia monosperma*, *Reaumuria palestina*, *Salsola villosa*, *Suaeda palestina*, and *Zygophyllum dumosum*). Some are wintergreen shrubs, losing their leaves in summer (e.g., *Lycium arabicum* and *Anagyris foetida*), whereas some (generally dwarf-shrubs) shed their leaves but retain evergreen stems, as in *Retama* and *Calligonum* species. Some have grayish, soft, deciduous leaves but keep smaller leaves during the summer (e.g., *Artemisia herba-alba*). Some are totally leafless, such as *Ephedra*. Perhaps most interesting are the leafless shrubs with modular stems and green, photosynthetic but disposable bark segments (e.g., *Haloxylon persicum* and *Anabasis articulata*). Many of these desert dwarf-shrubs extend well into the region of cold-winter continental deserts, in Middle and even Central Asia.

Where more water is available, there may be scattered trees such as acacias, deciduous thorn-shrubs such as *Noaea*, or desert grasses such as *Aristida*. Date palms (*Phoenix dactylifera*) occur around oases, where groundwater is reliable and near the surface. If seasonal pools form, small marshes of sedges and reeds occur. Halophytes include species such as *Halocnemum strobilaceum* on very saline sites and *Nitraria retusa* in brackish water. Deciduous but otherwise juniper-like tamarisk trees (*Jamarix* spp.) also occur where groundwater can be reached, generally at greater depth.

These dry areas are the landscapes of Judaism, Christianity, and Islam. These are also the landscapes of animals such as camels, which sweat but tolerate enormous loss of body water, and the oryx and eland, which pant to moisten nasal sinuses, thus cooling the blood supplied to their brains. There are also many rodents, living in underground burrows and foraging only at night, as well as ectothermic lizards and other reptiles. Most birds spend less time in deserts but may still be dependent on desert ecosystems during the cooler season, migrating to northern Eurasia in summer.

The two main mountain ranges in the subtropical desert zone are the Hejaz (Yemen and southwestern Saudi Arabia) and the Zagros and other mountains of southern and central Iran. The montane belt of the Hejaz contains dry juniper woodlands (*Juniperus*).

Mediterranean Ecosystems

Mediterranean-type climates have cool winters with some precipitation and long, dry summers with no significant precipitation perhaps for several consecutive months. As a result, the primary growing season is restricted to springtime, when

temperatures are increasing and soil water is readily available. Plant activity may continue into the summer as long as root systems can still reach deeper soil water. A shorter, secondary growing season often occurs in the autumn, when westerlies again bring some precipitation but before temperatures drop too low. The most characteristic plant adaptation to this climate is woody vegetation with deep root systems and hard (sclerophyll) evergreen leaves, often with waxy cuticles and/or oily secondary compounds which retard water loss from exposed surfaces. This type of "mediterranean sclerophyll" vegetation occurs in all five of the world's mediterranean-climate regions and represents a striking example of convergent evolution. The mediterranean region of Eurasia lies mainly between southern Europe and North Africa but extends eastward along the coastal rim of western and southern Turkey, to Cyprus, and eastward from Syria, Lebanon and Israel to more continental Iraq, the southern Caucasus region, and Iran.

Three general types of mediterranean landscapes can be recognized, differentiated primarily by total water availability. Where sufficient soil water can be reached throughout the year, forests composed of sclerophyll oaks such as *Quercus ilex* covered the Mediterranean borderlands (more in the more humid west) before they were cut by the ancient Romans to build their navies. Where less but still some water is available through the summer, perhaps at greater depth, the landscape is dominated by the characteristic dense sclerophyll woodlands and scrub denoted by their French name *maquis*. Where soil water is not available through the summer, more open stands of smaller, summer-deciduous dwarf shrubs dominate landscapes generically called *garrigues* (which may be patchy and may include some sclerophylls). Other plant types, however, also occur in mediterranean ecosystems on permanently more moist sites, including more water-demanding, evergreen laurel, myrtle, oleander, and even soft-leaved, winter-deciduous shrubs.

The Mediterranean region of Eurasia has been settled and modified by humans for several millennia, with consequent massive soil erosion and other degradation. As soil was lost, both soil water-holding capacity and local precipitation were reduced, resulting in replacement of forest and woodland by various types of garrigues in typical degradation stages.

In Mediterranean mountains, where winter temperatures may become too cold for sclerophylls, dry forests of pines are common, especially in Turkey. Cypressess (*Cupressus* spp.) and true cedars (*Cedrus*) may also occur, the latter occurring only in the mediterranean mountains of Lebanon (*C. libani*) and Cyprus (*C. brevifolia*), in the Atlas Mountains of northwestern Africa (*C. atlantica*), and in the drier western part of the Himalaya (*C. deodara*). Summergreen trees may also appear in mediterranean mountains and may form deciduous forests in sub-mediterranean borderlands (mainly in Europe), in continental areas with colder winters (such as the southern Caucasus and northern Iran), and on particular biotopes such as continuously moist flood-plains.

Many of the familiar mediterranean plants of the more humid western Mediterranean do not extend into the Asian region to the east. In particular, the stem-evergreen "broom" form of the western Mediterranean and Atlantic Europe (genera *Genista*, *Cytisus*, etc.) appears not to be important in southwestern Asia. Some species, however, extend throughout

the western and eastern Mediterranean areas, such as *Quercus cerris*, *Ceratonia siliqua*, *Juniperus oxycedrus*, *Myrtus communis*, and *Pistacia lentiscus*. Others are replaced to the east by similar species, such as *Quercus calliprinos*, *Qu. ithaburensis*, *Pistacia palestina*, and *Pinus brutia*. On the other hand, some species widespread throughout the Mediterranean region may have come originally from the east, such as Aleppo pine (*Pinus halepensis*). The vegetation of mediterranean Asia is well described by Zohary (1973, pp. 130–165).

Temperate Grasslands

In temperate Asia, especially in the west but also in the east, precipitation decreases southward while temperatures increase. As a result, climatic dryness increases southward and the temperate grasslands of Asia occur primarily in a rather narrow corridor that extends east–west across the continent, from the Black Sea region to northeastern China, between the boreal forest to the north and drier semi-desert and desert areas to the south. The Russian-derived term “steppe” normally means a short, discontinuous grassland in English-language ecology but is traditionally used in Asia for all grasslands. The Asian grassland zone can be divided as follows:

1. A discontinuous strip of “forest steppe” in the north (mainly *Populus* and *Betula*), analogous to the aspen “grove belt” of North America
2. A zone of tall-grass “meadow steppe” with many colorful forb species, analogous to the tall-grass prairies of North America
3. A zone of shorter, more open steppe, less developed north of the Black Sea but widening east of the Caspian and extending southward toward the desert areas of Turkestan and the Gobi

This zonation, its soils, and steppe ecosystems have been well described in the Russian ecological literature, much of which is essentially unknown in the West. In China also, scientific study of the grasslands (and other vegetation regions) goes back well before the Communist period but is unknown in the West.

The Eurasian steppe corridor is broken, largely by the Altai Mountains, into the Russian–Siberian steppes and the grasslands of Mongolia and northern China (Lavrenko as cited in Walter, 1974, pp. 163–165). In the western section, the steppe is composed especially of *Stipa* species, such as *Stipa capillata*, *S. lessingiana*, *S. stenophylla*, and other important grasses such as *Festuca sulcata*, *Koeleria gracilis*, *Dactylis glomerata*, *Poa botryoides* and other *Poa* spp., various *Agropyron* spp., *Bromus inermis*, and species of *Carex*. Especially characteristic of the western steppe are the many small geophytes (“ephemeroids”; Walter, 1974) from genera such as *Tulipa*, *Crocus*, *Ornithogalum*, *Bulbocodium*, and *Hyacinthella* as well as *Poa bulbosa*. Tall forbs in the meadow-steppe include *Anemone patens*, *Adonis vernalis*, *Salvia nutans*, *S. superba*, and *Delphinium confusum*. These are accompanied by some shorter shrubs and semishrubs, including the genera *Spiraea*, *Caragana*, and *Artemisia*. The main tree species in the forest-steppe, a wooded tall-grass prairie, are *Quercus robur*, *Betula verrucosa*, and *Populus tremula*.

In the mountains of Middle Asia, montane steppes occur below 2000 m and taller meadow-like grasslands above, including a park-like forest-steppe transition. These may involve grasses such as *Alopecurus pratensis* and *D. glomerata* and tall forbs, such as *Delphinium confusum*, *Ligularia altaica*, *Aquilegia sibirica*, and *Scabiosa alpestris*.

The grasslands of Central Asia, east of the Altai Mountains, involve mainly the Mongolian steppe and the grasslands of Manchuria. In the Mongolian steppe the most important grasses are *Stipa* species such as *S. krylovii*, and *Aneurolepidium chinense*, plus *K. cristata*, *F. sulcata*, and *P. botryoides* from the west. These are joined by xeric shrubs such as *Caragana* species and *Artemisia frigida*. The Manchurian grassland is largely a meadow-steppe dominated by *Aneurolepidium chinense*, along with *A. pseudo-agropyron* and *Stipa baicalensis*, plus forbs such as *Tanacetum sibiricum* (Compositae) and xeric shrubs such as *Artemisia sibirica* (Walter, 1974). On the lower slopes of the southern Hinggan Mountains is a forest-steppe transition to montane forests of *Larix dahurica*, *Betula platyphylla*, and more temperate forests of *Quercus mongolica*, *Tilia mongolica*, and *Pinus tabulaeformis*.

The development of the world’s temperate grasslands is closely linked with populations of large ungulates, such as the well-known bison of North America. In Eurasia some of the larger animals, most highly endangered, include Przewalski’s horse (*Equus przewalskii*), the Saiga antelope (*Saiga tatarica*), the Zheirhan gazelle (*Gazella subgutturosa*), and the wild camel (*Camelus ferus*). The ranges of these and many smaller grassland animals also extended into the adjoining semi-desert and desert zones. Smaller animals include many rodents, such as jereboas, gerbils, and small hamsters.

Temperate Semi-deserts and Deserts

The temperate deserts and semi-deserts of Asia, with cold winters, occur south of the temperate grasslands in three general areas (Walter and Box, 1983):

1. In Middle Asia (Turkestan), from the Caspian Sea (below sea level) to the foothills of the Altai and Tien Shan mountains
2. In Central Asia, including Dzungaria (northern Xinjiang), southern Mongolia (Gobi), part of Chinese Inner Mongolia (e.g., Ordos desert), the Tarim Basin (southern Xinjiang), and the smaller Tsaidam Basin (Qinghai), all approximately 500–1500 m above sea level
3. On the high, cold Tibetan Plateau, with an average elevation of approximately 4000 m

Separating Middle and Central Asia is the Tien Shan mountain system, running generally from southwest to northeast. This complex mountain system, with the associated Pamir to the south and Altai to the north, rises from the dry continental interior and constitutes to some extent a multi-zonal orobiome of its own (Walter and Box, 1983), with well developed coniferous forests related more to those of humid eastern Asia.

The climates of the temperate deserts are warm to hot in the summer (except for Tibet) and severely cold in the winter, except in the southern parts of Middle Asia (Turkmenistan), near the Iranian border. Precipitation in Middle Asia occurs

mainly in the spring and autumn, with very scant snow cover in winter and essentially no precipitation in summer. In Central Asia precipitation is confined almost completely to summer, brought by monsoon storms which manage to penetrate into the continental interior. Soils in all regions are coarse and skeletal, salinized in areas of internal drainage. The Central Asian deserts are totally continental and separated from the subtropical deserts of southwestern Asia. Although the Middle Asian deserts share some species with the subtropical deserts, they also are distinct from the subtropical deserts, both climatically and physiographically, separated by the Kopet Dag and other mountains of Iran and Afghanistan.

Middle Asian Deserts

A characteristic of the sandy deserts of Middle Asia is the dominance of both small, typical and much larger xeromorphic shrubs, some leafless and some at least partly evergreen. Reaching 2 m in height, leafless *Haloxylon persicum* extends over the whole region and even into the Gobi desert. It is joined in the Kara-Kum desert by *H. ammodendron*, a leafless tree form reaching 8 m in some locations. This is the only cold-winter desert region in the world in which a tree form gains even local dominance. Other important desert shrubs include *Artemisia pauciflora*, *A. terrae-albae*, *Halostachys caspica*, *Anabasis salsa*, *Halocnemum strobilaceum*, and *Kochia prostrata*, along with steppe and desert grasses such as *Festuca sulcata*, *Stipa capillata*, *Koeleria cristata*, and *Agropyron repens*. In areas of flat terrain and finer soil, mini-geophytes such as *Poa bulbosa* form vernal carpets of miniature flowers (Walter, 1974, p. 254).

Dzungaria, Gobi, and Tarim Basin

Dzungaria is the region east of the Dzungarian Gate, a gap in the Tien Shan–Altai mountain system, and extends across northern Xinjiang. This corridor between Middle Asia and the Gobi, as well as the Gobi itself, represents a region of rockier substrates and deserts dominated by typical desert shrubs such as *Artemisia*, *Anabasis*, and *Calligonum*. The most important grasses are *Stipa* bunch-grasses. Isolated trees of *Populus diversifolia*, *Tamarix ramosissima*, and occasionally *H. ammodendron* may occur along streams.

The Takla Makan (Tarim Basin), on the other hand, is a large sand sea within the horseshoe (open to the east) formed by the Tien Shan on the north, the Pamirs in the center, and the Karakoram and Kunlun ranges on the south. Together they form one of the most effective rain shadows in the world, and precipitation has very rarely ever been recorded in the Tarim Basin. There is little vegetation on the shifting sand areas, but runoff from the mountains does generate intermittent and permanent streams which extend into the basin. Along these streams one can find riparian strips of the phreatophytic *Tamarix ramosissima* as well as the widespread *Populus diversifolia* and *Ulmus pumila*. In some areas there are even extensive marshes of *Phragmites*, *Typha*, and *Scirpus* species, which are especially important for the large numbers of birds which overwinter in India and migrate to Siberia for the summer.

Tibetan Plateau

The high, dry Tibetan Plateau (average elevation approximately 4000 m) is a region of dry steppes, alpine mats (especially of *Kobresia* species), dwarf conifer scrub of *Juniperus*

and *Sabina*, and other sparse, low-growing, often cushion-shrub vegetation adapted to the harsh conditions. Many familiar genera from Central Asia (and Middle Asia) are represented, including *Caragana*, *Reaumuria*, *Acanitholimon*, *Astragalus*, *Tanacetum*, *Artemisia*, *Ptilagrostis*, and *Festuca*. Some familiar species also extend into the Tibetan highlands, including *Eurotia ceratoides* and *Kochia prostrata*. East Asian elements are important only in the east but include *Gentiana*, *Primula*, *Saxifraga*, *Saussurea*, and *Rhododendron*. Holarctic elements are few, but some are very abundant, especially in the alpine mats and marshes: *Kobresia*, *Carex*, *Eleocharis*, *Eriophorum*, and *Juncus*. Where moisture permits, subalpine tall-forb stands include such genera as *Aconitum*, *Delphinium*, *Ligularia*, *Polygonum*, and *Rheum*. These different geoelements all represent taxa which migrated into Tibet after the last glaciations.

Humid Monsoon Asia (Extratropical)

Monsoon Asia is the region dominated by the seasonally alternating monsoon wind system, which brings wet oceanic air masses onshore in the summer and blows dry and cold outward from the continental interior in winter (mainly eastward and southward). The region lies east of the Altai–Tien Shan mountains and extends from southern Siberia, through China, to Korea and Japan in the east and to tropical Asia in the south. In most of this region the only major mountains run east–west, so mean winter temperatures are low but outbreaks of even colder Siberian air are largely excluded. Except toward the interior, summer brings adequate rainfall throughout for forest growth. In fact, in Japan and some parts of eastern China, there is rarely any climatic drought and forests can be very mesomorphic. Humid monsoon Asia (i.e., forested East Asia) can be divided into two regions: (i) temperate deciduous forest in the typical-temperate and cool-temperate areas to the north and (ii) evergreen broad-leaved “laurel” forest in the warm-temperate and humid-subtropical zones to the south. Pine forests are important secondary landscapes in both areas. Mountains in East Asia are especially interesting for the rich variety of endemic conifer taxa which they contain.

Laurel Forest (Evergreen Broad-leaved Forest)

Laurel forests are evergreen broad-leaved forests of warm-temperate and humid-subtropical climates, dominated by trees with intermediate-sized, dark green (shade-tolerant), thin-coriaceous but mesomorphic leaves (laurophylls) such as are especially characteristic of the laurel family (Lauraceae). Forests dominated by laurophyll trees are rather dark and somber, with low light levels below the canopy, and are evergreen from top to bottom. In some respects laurel forests can be thought of as an extension of the tropical rain forests into the warm-temperate zone. East Asia contains the world's largest area of such forests, due to its abundant rainfall and winters without severely low temperatures, at least in coastal areas or on islands. Laurel forests occur generally south of about 35° N latitude but extend to 38° N on both sides of Japan. Counterparts occur in southern Brazil and small areas

of eastern Australia, as well as moist depressions ("bay forests") in the southeastern United States. Cool-temperate analogs occur in New Zealand and Tasmania.

In East Asia, laurel forests occur in southeastern China, in drier southwestern China (Sichuan and Yunnan, with different but largely vicariant species), in southern Japan, and in a small strip across southernmost Korea (Wang, 1961). In Southeast Asia, laurel forests also ascend into the mountains to form montane forests just above the tropical seasonal evergreen forests of the lowlands (Whitmore, 1984; Ohsawa, 1995). The main canopy tree genera of laurel forest are *Persea* (= *Machilus*), *Cinnamomum*, *Beilschmiedia*, etc. (Lauraceae); *Castanopsis*, evergreen *Quercus* (= *Cyclobalanopsis*), and *Lithocarpus* (Fagaceae); *Schima* (Theaceae), *Ilex* (Aquifoliaceae), *Michelia* (Magnoliaceae), and others, all with very similar laurophyll physiognomy. Understory trees and arborescents are largely from the same families. Lauraceae tend to be especially important in more perhumid (e.g., coastal) areas, whereas evergreen Fagaceae tend to become more important inland, especially in southwestern China.

In humid East Asia, the largest species turnover between the polar region and the tropics occurs within the bioclimatic zone of evergreen broad-leaved forests—without major change in the forest physiognomy. This occurs in the Okinawa Islands of Japan and in southeastern China, as temperate species abruptly disappear, including many laurophyll tree species, and are replaced by an essentially tropical flora which includes many new tree genera with essentially the same evergreen broad-leaved structure.

Temperate Deciduous Forest

The temperate deciduous forests of East Asia cover the northern half of Japan (including Hokkaido), most of Korea, and the northeastern part of China, especially Manchuria. This region is smaller than the region of evergreen broad-leaved forest and smaller than the deciduous forest region in eastern North America. Field estimates of primary productivity in Japan suggested that the deciduous forests were less productive than in North America and less productive than some montane conifer forests of Japan. Nevertheless, the deciduous forests of East Asia appear to have more species and genera, including almost all genera found in eastern North America (except *Carya*) and in Europe, plus some additional ones (e.g., *Cercidiphyllum*).

Japan and Korea

The deciduous forests of Japan are especially rich, due perhaps to the perhumid maritime climate and total lack of water stress during the growing season. Deciduous forests cover most of northern Honshu, dominated mainly by *Fagus crenata* but with many other taxa, such as *Fraxinus lanuginosa*, *Tilia japonica*, and *Magnolia obovata*. Understories are rich with maples (e.g., *Acer mono*, *A. japonicum*, and *A. palmatum*) and other mesic understory elements such as *Styrax obassia*, *Sorbus alnifolia*, *Cercidiphyllum japonicum*, *Aesculus turbinata*, *Callicarpa japonica*, *Hamamelis obtusata*, *Viburnum*, and *Euonymus*. One interesting transitional forest type occurs in parts of northeastern Honshu and involves co-dominance by *F. crenata* and

Abies firma, a temperate-zone fir. Forests of *Fagus japonica* generally occur only in the areas of transition to warm-temperate forest. An especially characteristic feature of the deciduous *Fagus* forests of Japan is the prevalence of short but broad-leaved bamboos of the genus *Sasa* (and recently also *Sasamorpha*), which form dense understories 0.5–1 m high where there is continuous snow cover. Other common herb-layer taxa include *Disporum*, *Viola*, *Chimaphila*, *Mitchella*, *Carex*, and ferns. Floodplain and other especially moist forests are dominated by ashes (*Fraxinus sieboldiana* and *F. spaethiana*), elms (e.g., *Ulmus davidiana*), *Pterocarya rhoifolia*, and other typical floodplain taxa (e.g., *Alnus hirsuta*). Also belonging to the temperate zone are the hemlock (*Tsuga sieboldii*) forests which occur most commonly on rocky substrates at the base of lower mountain slopes. Drier areas (still without water deficit) are generally covered by deciduous oak forests, including interior areas, lower mountains (e.g., *Qu. serrata*), and most of Hokkaido (*Quercus mongolica* var. *grosseserrata*).

The deciduous forests of Korea occur in a distinctly more continental climate, in which oaks (e.g., *Quercus mongolica*), and also *Carpinus*, become more important. Much of the Korean landscape is still recovering from the Korean War, after which the southern part was seeded with North American pines. In deciduous forest areas of both Japan and Korea, as in the evergreen forest region, native pines such as *Pinus densiflora* play a very important role in successional landscapes.

Manchuria and Eastern China

The forests of northeastern China and the Amur valley have a shorter growing season than in Japan but are still very rich. Canopy trees may include such species as *Quercus mongolica*, *Fraxinus mandshurica*, *Tilia amurensis* and *T. mandshurica*, *Ulmus macrocarpa* and *U. davidiana*, *Phellodendron amurense*, *Maackia amurensis*, *Juglans mandshurica*, *Acer mono*, *Betula dahurica* and *B. costata*, and *Populus koreana* and *P. ussuriensis*. A common temperate conifer in these forests is *Pinus koraiensis*. Understories may include trees of mainly the same species plus shrubs such as *Corylus heterophylla*, *Deutzia amurensis*, *Euonymus pauciflora*, *Philadelphus schrenkii*, *Syringa amurensis*, and *Viburnum* spp.

Further south, in northern, eastern, and into southeastern China, the deciduous and evergreen broad-leaved forests are almost totally destroyed by millennia of human habitation. As a result, it is difficult even for local scientists to identify the boundaries of the two forest regions. In hill and mountain areas of northern China (Liaoning, Shandong, Hebei, and Beijing) remaining mature forest types are dominated by *Quercus mongolica*, *Qu. liaotungensis*, and other *Quercus* species along with *Celtis*, *Fraxinus*, *Tilia*, *Betula*, and *Ulmus* as subordinate canopy elements. Understories may have elements such as *Lindera obtusiloba*, *Corylus heterophylla*, *Lespedeza bicolor*, and *Spiraea trilobata*. *Betula* and *Populus* forests occur as secondary types. *Quercus variabilis* forests occur as transitional forests south of the main deciduous forest region.

Among the most interesting deciduous forests are those involving various species of beech (*Fagus*), generally covering small areas at elevations from 1300 to 2200 m in central eastern China (Zhejiang to Guizhou provinces). Deciduous trees in interior southern China may have only short leafless periods. This is also one of very few areas in the world in

which deciduous and evergreen broad-leaved trees coexist in semi-evergreen broad-leaved forests.

Pine Forests

Pine forests represent extensive landscapes in East Asia due to long histories of continuing forest cutting. Until after World War II, many of the evergreen broad-leaved forest areas were managed as coppice forests. Other areas, however, were burned and cleared much earlier. In hilly and mountainous terrain, soil erosion followed clearing and broad-leaved forests could no longer recover. These areas usually became pine forest and were maintained by intermittent natural and induced burning of the understory. Much of southern Japan, the Korean peninsula, and upland warm-temperate and subtropical China are now covered by such pine forests.

In Japan, Korea, and some parts of northeastern China, these secondary pine forests are mainly dominated by *Pinus densiflora*. In eastern and southeastern China, pines with more warm-temperate to subtropical distributions become dominant, especially *P. massoniana* and *P. tabulaeformis*. In southwestern China, forests of *P. armandii* occur in Sichuan and on the Yunnan plateau, whereas subtropical pine forests of *P. kesiya* (cf. *P. khasya*) become important in the mountainous transition southward into lowland Xishuangbanna and the mountains of northern Thailand. In addition to pine, the warm-temperate to subtropical "Chinese fir" (*Cunninghamia lanceolata*) is also important in secondary landscapes and, like pine, is widely planted.

Mountains of Humid East Asia

The mountains of East Asia represent the only large mountainous area in the warm-temperate and humid subtropical zones of either hemisphere (although smaller areas do occur in Mexico, southern Brazil, eastern Australia, and northern New Zealand). The various mountain systems of humid East Asia, including at least the more humid eastern Himalaya, thus represent areas of unusual diversity and endemism, especially among what appear to be relict conifers. Endemic conifer genera include *Amentotaxus*, *Cathaya*, *Cephalotaxus*, *Keteleeria*, *Cryptomeria*, *Cunninghamia*, *Fokienia*, *Glyptostrobus*, *Sciadopitys*, *Taiwania*, and *Thujopsis*, at least some of which once occurred more widely. In addition, more widespread conifer genera such as *Abies*, *Chamaecyparis*, *Picea*, *Taxus*, *Thuja*, and *Tsuga* have relatively high species diversity in these areas. In most of the area, the lowland biome is evergreen broad-leaved forest, which may extend well into the montane belt in most places, with well-developed *Rhododendron* belts and a more warm-temperate character. As winter becomes colder upward, summergreen deciduous forest may occur, but the forest may also grade directly into evergreen high-mountain conifer forest. None of these warmer mountain systems is high enough to have an alpine belt except the Himalaya.

In the western Himalaya, montane conifer forests are dominated by *Pinus roxburghiana* and the deodar cedar (*Cedrus deodara*), a preferred ornamental tree throughout the world. To the northwest, in the Tien Shan and Altai systems, the montane conifer forests are simpler, dominated often by *Picea*

schrenkiana but including forests of shade-tolerant *Pinus sibirica* as well as boreal *Picea* and *Abies*, larches, and *Pinus sylvestris* (Walter, 1974; Walter and Box, 1983, Chap. 7). In western Tibet, the main conifers are *Abies delavayi* and *A. webbia*, along with *Picea likiangensis*. This is also the area of the dawn redwood (*Metasequoia glyptostroboides*), first identified from fossils, only discovered in the wild in the early 1900s but now widely planted as a street tree throughout China.

Extensive evergreen oak forests, involving *Quercus semicarpifolia* and many other species, still occur on the southern slopes of the Himalaya and may represent a somewhat unique warm-temperate forest biome. At higher elevations, *Betula albosinensis*, *Acer tetramerum*, and many other deciduous species form belts of summergreen forest in some areas. Subalpine conifer forests may contain species such as *Picea likiangensis* (better known from Manchuria), *Abies squamata* and *A. georgei*, *Tsuga dumosa*, and even the deciduous *Larix potaninii*. The best developed *Rhododendron* belts are in the eastern Himalaya.

On the lower parts of the eastern Tibetan Plateau, *P. likiangensis*, *A. squamata*, and *A. georgei* form tall coniferous forests, followed upward by *Abies faxoniana*, *Picea asperata*, and *P. noveitchii* (Archibold, 1995). *Larix* may be admixed, and *Sabina* and *Cupressus* form shorter woodlands in drier areas. Toward the Yunnan Plateau to the southeast, *Tsuga yunnanensis* becomes important, with *Picea brachytyla* and *Abies fabri* at higher elevation. At lower elevation, the eastern Tibetan Plateau (mainly in Sichuan) also contains two of China's biological treasures: the range of the Giant Panda at the Wolong Preserve and E-mei Shan (3099 m), one of China's four sacred mountains, with a well-developed zonation (and footpath) from laurel forest to subalpine conifer forest of *A. fabri*. To the south, at elevations not higher than about 1500 m on the Yunnan Plateau, smaller areas of laurel forest remain in the Ailao Shan and other ranges southward into Xishuangbanna.

In the transition region of eastern China (summergreen to evergreen laurel forest), two other accessible mountains also have well-developed zonations, which are botanically well described: Huang-Shan in southeastern Anhui province and Tianmu-Shan in northern Zhejiang province. The mountains of Taiwan are especially steep, and the montane laurel forests are consequently relatively well preserved.

In northeastern China, along the Korean border, the vertical zonation of the Changbai-Shan can be described as follows:

- 0–500 m: summergreen deciduous forest
- 500–1100 m: mixed deciduous and conifer forest (*P. koraiensis* plus much secondary forest of *Betula platyphylla*)
- 1100–1700 m: coniferous forest (*Picea jezoensis* var. *komarovii*, *P. koraiensis*, with *Abies nephrolepis*, *Acer*, *Betula*, *Sorbus*)
- 1700–2000 m: Birch woodland and krummholz (*Betula ermanii*)
- 2000–2600 m: Alpine tundra, mostly heath of *Vaccinium uliginosum* and *Dryas octopetala*, plus *Rhododendron aur-eum*, *Rh. confertissimum*, etc.
- 2600–2700 m: Alpine cold-desert (snow still just melting in early September)

Further to the north, larch forests dominated by *Larix gmelini* occur in the northern Da Hinggan Mountains near the Siberian border (Missouri Botanical Garden, 1983; Wang, 1961).

Montane forests and zonation in Korea can perhaps best be seen on Mt. Seolag (1308 m). The zonation is similar to that described for Changbai-Shan but with a greater importance of deciduous *Quercus* and *Carpinus* forests at low elevation and the lack of an alpine belt.

The mountain vegetation of Japan has been very extensively studied and described in the evergreen as well as the deciduous forest zones (Numata, 1974). Among the most impressive native coniferous forests of Japan are the tall forests of *Cryptomeria japonica* occurring on Yakushima island and in some areas with more than 3000 mm of precipitation on Shikoku and Honshu. These forests could be called temperate rain forests. Forests of *Chamaecyparis obtusifolia* are also tall and impressive. Other montane conifers in Japan include *Abies homolepis*, *A. mariesii*, and *A. veitchii* mainly on Honshu; *A. sachalinensis* mainly on Hokkaido; *Picea jezoensis* (Hokkaido) and *P. glehnii*; *Larix leptolepis* (on old lava); *Tsuga sieboldii* (lower mountains) and subalpine *Ts. diversifolia*, *Thuja standishii*; and *Thujopsis dolobrata* (endemic genus).

In most of northeastern Asia, the subalpine belt is characterized by dense stands of the krummholz species *Pinus pumila*, which also occurs in Siberia. In more maritime areas approaching the boreal zone, such as Hokkaido, conifers may be replaced by forests of birch, especially *B. ermanii*.

Boreal and Polar Asia

Boreal and polar Asia extends from the Ural Mountains to the Pacific Ocean and from islands in the Arctic Ocean to the transition to temperate climates in the south, approximately along the southern boundary of Siberia. In Europe, this transition takes the form of mixed boreo-nemoral forests of deciduous broad-leaved trees and conifers, narrowing eastward from Poland through Moscow and on to the Urals around Sverdlovsk. In Asia, this transition is a more discontinuous zone of mixed forests and forest-steppe, running from the southern Urals past the southern end of Lake Baikal and on to northeastern China, where it widens again between the Siberian larch taiga to the north and the deciduous forests of Manchuria. In the middle section, the transition is mainly a narrow belt of aspen (*Populus tremula*) and birch parklands between subboreal or boreal forests to the north and the grasslands of Mongolia to the south.

During the Pleistocene, much of Siberia remained unglaciated but covered by tundra and cold steppe vegetation, which extended southward to the grasslands with no intervening coniferous forest zone. The boreal forest which now covers most of Siberia is thus a relatively recent phenomenon. This boreal forest is mainly an evergreen coniferous forest in the west but opens to lighter larch (*Larix*) forest and woodland in the east, where winters are most severe. The west-Siberian lowland is a vast complex of boreal forest and wetlands, whereas northeastern Siberia is quite mountainous. The larch region of interior eastern Siberia contains the most continental climates in the world, with mean July temperatures usually exceeding 20 °C but with mean January temperatures generally near or below –30 °C, reaching –51 °C at Oimyakon and Verkhoyansk in the northeast. The transition to polar tundra involves a zone of open forest–tundra

woodland, which reaches its farthest point north (in the world) in the Taimyr Peninsula of northwestern Siberia. Polar tundra forms a narrow belt along the northern coastal plain completely across Eurasia.

Boreal Forest

If the subboreal zone is included, four main types of boreal forest can be recognized (Walter, 1974):

1. Mixed forests of summergreen broad-leaved trees and conifers (mainly *Picea* and *Pinus*), along with localized pine forests
2. Dense forests of spruce (*Picea*), fir (*Abies*), and five-needle pine (*Pinus sibirica*)
3. More open forests and woodlands of Scots pine (*Pinus sylvestris*)
4. Generally open forests and woodlands of larch (*Larix*), a genus of deciduous conifers

Of these, the dense forests of spruce, fir, and Siberian pine are generally called “dark taiga,” whereas the more open forests and woodlands of pine and larch are called “light taiga.”

Boreo-nemoral mixed forests, with *Acer*, *Tilia*, *Ulmus*, *Fraxinus*, *Quercus*, *Picea*, *Pinus*, etc., are better developed in eastern Europe than in Asia but reappear in Manchuria and the Russian Far East and some smaller areas such as the subboreal region on the west side of Lake Baikal. In more continental areas, *Betula* and *Populus* may be the only important broad-leaved trees, and pines may be the main conifers, especially if the soil is coarse and less humic. At the southern end of Lake Baikal (52–54° N, 450 m), boreo-nemoral mixed forests can be found in moist alluvial lowlands, whereas dark taiga, with larch and five-needle pine, occurs on uplands higher than about 700 m.

Dark taiga is composed of shade-tolerant conifers, mainly Siberian spruce (*Picea obovata*), five-needle Siberian pine (*P. sibirica*), and Siberian fir (*Abies sibirica*). All three of these extend from the Urals into southeastern Siberia (if not completely to the Pacific). Dark taiga is limited geographically by the extreme winter cold, yielding to deciduous larch taiga generally where mean January temperature falls below about –30 °C (extremes to below –60 °C). The range of dark taiga is thus mainly European Russia through western Siberia and in a narrowing zone into southeastern Siberia. Within this range, dark taiga occurs over most of the area, with more open forests of *P. sylvestris* confined mainly to sandy, upland rock, or other drier substrates. In some smaller areas, mainly in mountains, other species of *Picea* and *Abies* appear as well as other five-needle pines such as *P. cembra* and *P. pumila*, often occurring as subalpine krummholz. Larches, often large, also occur widely as companion species within the dark taiga.

Scots pine (*P. sylvestris*) has the widest distribution of any tree species in Eurasia and covers large areas of light taiga throughout the European and Asian boreal zone and occurs in mixed forests in Europe, the Caucasus, and northern Manchuria. Boreal pine forests are usually open and have understories of two main types: *Cladonia* and similar lichens (plus mosses) on drier sites such as sand, and ericads such as *Vaccinium* on more moist sites.

Most of the boreal zone of central and eastern Siberia is covered by extensive open forests and woodlands of larch, especially *Larix dahurica* but also other species with smaller ranges. *Larix sibirica* is more important as a companion in the dark taiga of western Siberia. As in many higher latitude mountainous regions, the larch woods may occur mainly on slopes while flat valley bottoms remain largely treeless, a pattern attributed to cold-air drainage. The ground vegetation in these areas and in the larch stands as well is composed largely of boreal and tundra dwarf-shrubs such as *Vaccinium uliginosum*, *Ledum*, *Dryas*, and *Arctous*, plus abundant mosses and lichens. In moist areas shrubs from the genera *Juniperus*, *Salix*, *Alnus*, and *Betula* often become important understory elements.

The larch woods of interior northeastern Siberia in particular occur where annual precipitation is generally under 300 mm and sometimes under 200 mm. Although the growing season is thus a period of climatic water deficit, the trees survive from soil water which is effectively rationed to them over the course of the summer by the slow thawing of the soil (Walter, 1974, p. 84). Larches are outcompeted by evergreen conifers in some boreal areas but have no tree competitors in the coldest parts of eastern Siberia. Larch-dominated landscapes thus extend from the polar treeline across much of Siberia southward to Mongolia and into inland areas of the Russian Far East (Primorye and Khabarovsk provinces) and mountains of northernmost Manchuria.

Mountains within the boreal zone may quickly reach treeline. On lower slopes, however, the boreal forest may be somewhat different from the surrounding flatter lowlands. In the Ural Mountains, forests on the wetter western slopes generally involve *P. sylvestris*, *Abies sibirica*, *Picea abies*, *Betula pubescens*, and krummholz of *P. pumila*, whereas forests on the drier eastern slopes are mainly *P. sylvestris*. In less extreme, maritime areas of eastern Siberia, the deciduous larch taiga may be replaced again by evergreen conifers, such as *Abies nephrolepis* around the Sea of Okhotsk and *A. sachalinensis* on Sakhalin island (also northern Japan). Stunted forests of *B. ermanii* appear in the most maritime areas (e.g., Kamchatka, Sakhalin, and northern Japan).

Polar and Mountain Tundra

Polar ecosystems, generally called tundra, occur across the northern coastal plain of Eurasia but also in both upland and high-mountain situations, such as the lower mountains of boreal northeastern Siberia and the high Tibetan Plateau. Upland tundra in the boreal zone represents the first upward vegetation belt and is thus commonly called montane tundra. In high mountains, tundra-like ecosystems occur above the alpine treeline and are generally called alpine tundra. In all three situations, these are treeless landscapes dominated by mosaics of the following basic associations:

1. Largely evergreen, microphyllous dwarf-scrub on locally somewhat higher, drier areas
2. Wet graminoid vegetation in the lowest areas, generally flat, marshy depressions
3. Mixes of evergreen and summergreen plants, herbaceous and dwarf-shrub, including minigeophytes, on the broad, slight slopes between the higher and lower areas

4. Mainly mosses and lichens on the most extreme areas, including the coldest but also the most exposed upland areas where little snow remains

In mountains, two additional types can be identified. One is the "snow valleys" (Schneetälchen), depressions with deep snow accumulations which have shorter snow-free seasons and specialized floras composed of plants which can complete their life cycles in periods as short as one month in summer. The other is the extensive alpine mats, often dominated by *Kobresia*, found in drier high-mountain areas such as the Tien Shan, Hindu Kush, and Tibetan highlands, generally above 3000 m.

The polar tundra extends from extreme northern Fennoscandia across northern Russia to coastal northeastern Siberia in a narrow strip which is widest on the Taimyr peninsula. Due to continentality effects, however, the Taimyr is also the area where boreal forest extends farthest north, reaching about 72.5° N (as larch forest) north of Khatanga. On the flat coastal topography, herbaceous tundra is perhaps most extensive. The polar tundra can be represented zonally, however, in four subzones from south to north:

1. The transitional forest-tundra of largely dwarf-shrub tundra with scattered but still tall individual conifers (mainly larches in the east and spruces in the west)
2. Dwarf-shrub tundra, dominated largely by shrub forms from summergreen tree genera, mainly *Betula*, *Salix*, and *Alnus*
3. Largely herbaceous tundra with few dwarf-shrubs but still a continuous vegetation cover including many mosses and lichens
4. The discontinuous High Arctic cold-desert with vegetation restricted to more scattered individuals of a few vascular plants (especially *Dryas* spp.) and various lichens and mosses

The forest-tundra and dwarf-shrub tundra zones of the lowlands are better represented in western Siberia, but montane analogs are fairly widespread in the lower mountain areas east of the Lena River in eastern Siberia. Cold-desert, on the other hand, is a bit more widespread in the east and on the Arctic islands.

Two other prominent features of the polar zone are the prevalence of permafrost and substrates divided into stone polygons by frost action. Permafrost occurs where mean annual temperatures are below 0 °C, i.e., north of about 62° N continuously and discontinuously in uplands further south. Polygon substrates (and other features such as pingos) occur where seasonal freezing and thawing of "soil" which is largely water forces the larger solids (i.e., rocks) to the surface in a slow, bubble-like fashion that distributes them into polygons which become connected into polygon networks. The interiors of the polygons are lower, flat, and wetter, whereas the rocky borders, only 10–20 cm higher, represent drier biotopes.

Polar tundra in particular (including boreal montane tundra) involves many taxa with circumpolar distributions, including genera such as *Carex*, cotton grass (*Eriophorum*), and other sedges; many ericads (e.g., *Vaccinium*, *Arctostaphylos*, and *Cassiope*); other forbs, such as *Dryas*; and both evergreen dwarf-shrubs (e.g., *Empetrum*) and sometimes taller deciduous dwarf-shrubs (e.g., *Betula*, *Salix*, and *Alnus*). For nonvascular

plants, an even larger percentage of the taxa are circumpolar, including mosses such as *Sphagnum*, *Polytrichum*, and *Hylocomnium*, and lichens such as *Cladonia* and *Cladina*. As in the boreal zone, the flora of eastern polar Siberia is richer than that of western Siberia due to its lack of Pleistocene glaciation.

Most of the same genera, of vascular and nonvascular plants, also occur in the high-mountain tundra. Alpine tree-line in mountains of northern Asia is commonly formed by *P. pumila* krummholz, whereas the alpine tundra typically involves familiar heath taxa such as *Empetrum*, *Phyllodoce*, *Cassiope*, and *Dryas* as well as dwarf *Salix* and sedges. In general, however, alpine vegetation is more species rich than is corresponding polar tundra, perhaps due to the lack of permafrost and the greater number of microhabitats in the more heterogeneous terrain of high mountains. Many more localized species usually occur. Some important genera of Asian high mountains which are not important (if present at all) in polar tundra include *Geum*, *Gentiana*, and *Leontopodium*.

Despite its relatively low productivity, the polar tundra supports many animal species and in surprisingly large numbers, at least in summer. Caribou (reindeer) winter in the boreal zone and migrate to the tundra during the summer. Birds migrate from much greater distances away, some from as far as tropical Asia. Other birds, such as ptarmigan, overwinter near the polar zone. Mammals such as polar bears and some small rodents (e.g., lemmings) also live year-round in the polar zone.

Wetlands and Coastal Ecosystems

Wetlands include mangroves, other coastal ecosystems such as strand forests, beach vegetation, salt marshes, deltas, and estuaries and terrestrial wetlands such as swamp forests, marshes, bogs, and (*sensu lato*) even lakes and streams. Most wetlands are highly productive systems when not badly degraded, have important economic and social benefits for local human populations, and perform useful ecological services such as cleansing wastewater. Wetlands also support a wide range of animal life, often far beyond their own borders, as in the case of migratory birds, fish, and shellfish.

Mangroves are salt-tolerant forests growing in the intertidal zone, thus flushed by saltwater tides once or twice daily but also influenced by the inflow regime of freshwater runoff from the land. Behind many mangroves are so-called "back mangroves" which are less influenced by wave energy, generally less salty, and contain different and usually more species. Mangroves have developed in part by trapping fine sediment, so the mangrove substrate is usually deep mud (but also shallower mud and sand). As a result, mangroves are home to abundant burrowing shrimp, crabs, and other crustaceans as well as spiders, insects, and some birds. The total number of plant "mangrove species" in the world has generally been estimated at fewer than 100, involving especially the genera *Rhizophora* and *Avicennia* as well as particularly Asian genera such as *Bruguiera*, *Ceriops* and *Kandelia* (Rhizophoraceae),

Table 10 Mangrove areas in Asia

Country	Total mangrove area (ha)	Number of protected mangrove areas
East Asia		
China	67,000	24
Hong Kong	0	9
Japan (Ryukyu Islands)	400	4
Taiwan	174	4
Southeast Asia		
Brunei	7000	3
Cambodia	10,000	0
Indonesia (including Irian Jaya)	4,251,011	152
Malaysia	630,000	99
Myanmar	517,000	6
Philippines	400,000	59
Singapore	1800	2
Thailand	268,693	17
Vietnam (South)	370,000	2
South and Southwest Asia		
Andaman Islands	(50,000)	25
Bangladesh	410,000	5
India	306,000	9
Iran	23,717	3
Maldives	—	0
Pakistan	249,500	2
Sri Lanka	120,000	9
Arabian Peninsula		
Bahrain	40	1
Saudi Arabia, Oman, Qatar	—	0
United Arab Emirates	—	6
Yemen	—	5

Sonneratia, and *Aegiceras*. Back mangroves contain additional taxa such as *Lumnitzera*, *Xylocarpus*, the mangrove palm (*Nypa fruticans*), *Acanthus*, the widespread fern *Acrostichum aureum*, and even the buttressed tree *Heritiera littoralis* (Sterculiaceae)

in some cases. In areas protected from direct hits by typhoons, mangrove forests can grow to about 35 m in height. In more exposed areas, however, and in areas with shallower or hard mud, mangroves are reduced to only a few meters in height.

Table 11 Most seriously threatened wetlands in Asia

Bangladesh	Malaysia
Chalan Beel*	Sedili Kecil swamp forest
Haor Basin of Sylhet and Eastern Mymensingh	Klang Islands: Pulau Ketam*
Dubriar Haor*	Kapar Forest Reserve
The Sundarbans	North Selangor swamp forest
Wetlands in Pabla Khali Wildlife Sanctuary	Marintaman Mengalong*
Chokoria Sundarbans*	Tempasuk Plain
Bhutan	Lawas mangroves
Boomthang Valley	Trusan-Sundar mangroves
Burma (Myanmar)	Limbang mangroves
Irrawaddy Delta	Maludam swamp forest
China	Sarawak Mangrove Forest Reserve
Yancheng Marshes	Nepal
Shijiu Hu	Begnas Tal*
Shengjin Hu and the lower Yangtze Lakes	Pakistan
Shengjin Hu	Khabbaki Lake*
Xi Jiang (Pearl River) Delta*	Siranda Lake*
Tuosu Hu (Kurlyk Nor) and Kuerhleiko Hu	Hawkes Bay/Sandspit Beaches and adjacent creeks
India	Clifton Beach
Dal Lake	Korangi and Gharo Creeks
Wular Lake	The Outer Indus Delta
Harike Lake	Philippines
Jheels in the vicinity of Haidergarh*	Pangasinan Wetlands*
Dahar and Sauj (Soj) Jheels	Manila Bay*
Southern Gulf of Kutch	Laguna de Bay
Gulf of Khambhat	Tayabas Bay including Pagbilao Bay
Khabartal	Inabanga Coast
Dipor (Deepar) Bheel	Mactan, Kalawisan and Cansaga Bays*
Logtak Lake	Agusan marsh
Salt Lakes Swamp*	Lake Leonard*
The Sunderbans	Davao Gulf
Chilka Lake	Liguasan marsh
Kolleru Lake	Singapore
Estuaries of the Karnataka coast	Serangoon estuary*
Kaliveli Tank and Yedayanthittu estuary	Sri Lanka
The Cochin backwaters	Thandamannar Lagoon*
Wetlands in the Andaman and Nicobar Islands	Chundikkulam Lagoon
Indonesia	Chalai Lagoon*
Banyuasin Musi River Delta	Periyakarachchi and Sinnakarachchi Lagoons*
Muara Cimanuk*	Mahaweli Ganga floodplain system
Sukolilo	Maha Lewaya and Karagan Lewaya
Cilacap and Sagara Anakan	Lunama Kalapuwa and Kalametiya Kalapuwa*
Danau Bankau, other swamps of Barito Basin*	Bellanwillia-Attidiya marshes
Banau Sentarum	Taiwan
Wetlands in Manusela proposed national park	Tatu estuary
Wasur and Rawa Biru	Tungshih (Ton-Shou) mangroves*
Japan	Thailand

Source: Reproduced from Scott DA and Poole CM (1989) *A Status Overview of Asian Wetlands*, No. 53 AWB. Malaysia: Kuala Lumpur, via Groombridge (1992, p. 303).

In areas with higher salinity (drier climates and less freshwater inflow), mangroves are also shorter and may have saline lagoons behind them instead of more productive back mangroves.

Mangroves in Asia are considered to be the most diverse in the world and covered about 7.7 million ha at the time of the *Global Biodiversity* census (Groombridge, 1992). As shown in Table 10, most of this area was in Indonesia (about half in Sumatra), Malaysia (about half in Sabah), Bangladesh, the Philippines, Vietnam, India, Thailand, and Pakistan (see complete statistics in Groombridge, 1992, p. 325). Another 3 million ha belonged to Indonesia but are in Irian Jaya (New Guinea), which geologically is part of Australia, not Asia. These statistics are old, and mangroves have been declining steadily and often rapidly, being converted for development, urban sprawl, or mining (tin); cut for wood; or simply degraded by overuse.

On higher-energy tropical and subtropical coastlines, where the substrate is usually sand, the first beach pioneer inland from the water line is usually the creeping vine *Ipomoea pes-caprae* (Convolvulaceae). Behind this the first stable vegetation is often a dense thicket of large-sclerophyll shrubs, *Scaevola* (Goodeniaceae) and sometimes *Messerschmidia* (Boraginaceae), plus some pandans and various smaller species which elsewhere might pass as weeds. On many sandy tropical shorelines, coconut palms (*Cocos nucifera*) have established naturally or been planted and cultivated. Strand forests may develop behind beaches and on raised coral terraces, dominated by tree species such as *Pongamia pinnata*, *Ficus microcarpa*, and *Bischofia javanica*.

At higher latitudes, where winter cold precludes tropical taxa and the previously mentioned systems, salt marshes are the

most common shoreline ecosystem. These are also highly productive ecosystems, rivaling tropical rain forests in some cases, and can cover quite wide areas along more concave shorelines, where the intertidal range is higher and thus reaches farther inland. In east Asia, salt marshes extend as far north as the Russian Far East north of Vladivostok. Of course, estuaries also extend to higher latitudes and have been the basis for human settlement in coastal areas for millennia because of their abundance of fish and shellfish. All of these coastline ecosystems, though narrow, are important as buffers between the ocean and the more widespread, typical forests behind them.

Inland, the western Siberian lowland (between the Urals and the Yenisey River, about one-third of all of Siberia) is mostly a vast boreal swamp and may rank as the world's largest single wetland. Boreal landscapes in general, however, are often slowly shifting mosaics of forested uplands and lower lying fens and bogs. In the cold climate most bogs accumulate peat, which raises the land surface such that former depressions become convex surfaces fed only by nutrient-poor precipitation rather than groundwater. These are the highly acidic "raised bogs" which contain mainly ericaceous dwarf-shrubs (e.g., *Oxycoccus* and *Andromeda*), sedges (e.g., *Eriophorum*), and mosses, especially *Sphagnum* species. Around the edges of these (and other) bogs may be stunted birches, larches, and other trees tolerant of saturated soils and high acidity. Although individually small and not stable over long time scales, these bogs cover a very large area and store much carbon, which may be released to the atmosphere as global warming warms and dries these areas.

Bogs and (less acidic) fens also occur in the temperate zone to the south but especially in moist, cooler areas such as northern Japan. More important in drier climates are probably

Table 12 Original and remaining areas of tropical moist forest in Asia (km²)^a

the freshwater marshes, which are of great importance to birds migrating between wintering areas in tropical Asia (e.g., India) and summer breeding grounds in Siberia. Such marshes may occur in depressions as well as along streams, especially in the deserts of western China, the grasslands of northern China and Mongolia, and in Middle Asia and the highlands of Tibet. These marshes are composed primarily of reeds (*Phragmites*), cattails (*Typha*), sedges (*Cyperus*, *Scirpus*, and *Carex*), and similar herbaceous plants.

Among lakes and streams, the important ecological distinction is between more aerated, nutrient-rich flowing waters

and standing waters which can become quite oligotrophic, especially in cooler climates. Lake Baikal, in southern Siberia, is the world's deepest lake (1620 m) and contains about 20% of all the world's (unfrozen) fresh water. The lake contains about 600 plant species (35% endemic) and 1200 animal species (60% endemic). It is also large enough to produce a distinct limnoclimate around its edges, in which species from boreal and polar areas occur in small disjunct populations. Another well-known lake in Asia is Dal Lake in Kashmir, which has a flat bottom, is only a few meters deep, and has been filling rapidly over the past decades with sediment from

the surrounding mountains, which have been denuded largely since the 1950s. This and many other lakes are also extremely important for migrating birds. In temperate and tropical Asia, the large rivers are especially important, even though their ecosystems are often badly degraded or at least greatly altered by introductions of exotic species.

A listing of the most seriously threatened wetlands in Asia is shown in [Table 11](#). Some sites are denoted as already too degraded to merit any special conservation effort. Many other wetlands are not on this priority list but were or have since become threatened to the point that their biodiversity as well as their benefits to local human societies are being rapidly lost.

Artificial Ecosystems

One other class of ecosystems, especially important in long-settled Asia, is artificial ecosystems such as those involving tree plantations, urban landscapes, rice paddies, cropland, managed ponds, etc. Plantations of native conifers are especially extensive in the mountains of Japan, but much more widespread, especially in tropical Asia, are plantations of exotic eucalyptus, Australian pine (*Casuarina*), and other trees not from any part of Asia. Although these plantations, which mainly provide fuelwood, may take the pressure off more natural, native forests, they also damage the soil such that it no longer supports the normal diversity of soil and understory plants, animals, and microbes, especially decomposer organisms which break down and cycle minerals.

Rice paddies and cropland do support some degree of diversity among species which are commonly associated with certain types of management regimes. These largely weedy species may not be species of stable native ecosystems, but they do form somewhat consistent communities. Ponds and other water bodies managed for fish raising, etc. are also common in warmer parts of Asia. The species diversity is low and involves mainly exotic, weedy species such as *Myriophyllum* or water hyacinth (*Eichhornia crassipes*).

Urban landscapes are extensive and ever-growing in Asia as elsewhere. Urban ecosystems may involve allées and other plantings for landscape amelioration but may also involve seminatural wooded, grassy, and aquatic communities. Some of the methods for building semi-natural forests in densely built-up areas are quite well developed, especially in Japan (Miyawaki et al., 1987).

Conservation Status

The conservation status of natural and even of modified but functioning, quasinatural ecosystems in Asia varies widely. Some vast tracts of boreal forest appear untouched, but one cannot fly over these areas without seeing smoke (often industrial) rising from what appear to be very isolated places. Other forest areas have almost completely disappeared. It has been estimated that less than 1% of the natural evergreen broad-leaved forest area of Japan remains, and natural broad-leaved as well as conifer forests in China are confined

entirely to mountain areas, where they now are also facing encroachment. Tropical forests have also largely disappeared, remaining over large areas mainly in Southeast Asia (see [Table 7](#)). The especially well-developed tropical rain forests of Borneo, with canopy heights commonly near 50 m, have largely been cut within the past 20 years, mostly for export to Japan. Some estimates of original and remaining area of tropical rain forest are shown in [Table 12](#), but the data for remaining area (all pre-1990) must be overestimates.

Country totals of threatened plant and vertebrate species, and also fish, in Asia are summarized in [Table 13](#). Although these statistics reflect different levels of coverage and different methodologies, they give an indication of the magnitude of the problem of threats to biodiversity by changing conditions—mostly changes in land use by humans. Large numbers of threatened plants are recognized only in Turkey in the west, in Yemen on the Arabian Peninsula, in China in east Asia, and in India, Malaysia, Vietnam, and Sri Lanka in tropical Asia—although many others must also be threatened in other areas. The pattern for animals is more even across countries and regions, but with Indonesia or China recognizing the largest numbers of threatened species in all five categories.

Species and ecosystems are endangered throughout Asia, as elsewhere. For further reading, see in particular the various recent summaries of the status of conservation efforts and strategies in all parts of the world (Hoyt, 1994; Heywood, 1995) as well as more standard treatments of the general problems of wildlife conservation.

Glossary

Biogeographic region Region that contains a “homogeneous” suite of floristic groups sorted by some classificatory program.

Community diversity Number of ecosystems and associated plant and animal species per 1° latitude by 1° longitude grid-cell.

Diagnostic species Species that emerge from semiquantitative analysis as being the key species associated with a floristic group.

Evaporative aerodynamics Study of the influence of aerodynamics on the development of both leaf structure and foliage distribution throughout a plant community.

Floristic group Plant community that contains a “homogeneous” suite of species sorted by some classificatory program.

Foliage projective cover (FPC) The horizontal cover of leaves (in crowns of varying foliage density) in overstory and understory strata of plant community, measured using vertical cross-wire sighting tubes.

Shoot growth Biomass production (per hectare) of foliage shoots produced annually in the overstory of a plant community.

Species richness Number of species of plant or animal per hectare (per 100 hectares for rainforest remnants).

Outline

Species richness (number of species per hectare) of overstory and understory plants in floristic groups from arid to perhumid climatic zones in the tropical north to the temperate south of Australia, together with species richness of resident vertebrates and epigaeic invertebrates, is correlated with annual energy-fixation (per hectare) in each ecosystem.

Australian Ecosystems

Australia is a continental mass lying south of the equator between latitudes 11° and 44°. The climate varies markedly with geographical position: summer rainfall predominates in the north, winter rainfall is a characteristic of the south, and the eastern seaboard shows a more general distribution of rainfall throughout the year. Marked evaporative gradients from the humid coastal fringe to the arid inland are found in the south, east, and north of the continent. The structure of the vegetation varies along these evaporative gradients: from the dense rainforests in eastern Australia, to the tall eucalypt forests of the south-west and south-east (extending northwards at the fringe of subtropical and tropical rainforests), to the eucalypt forests/woodlands, with either grassy or heathy understory, distributed throughout the continent. Heathlands and grasslands are found in tropical to temperate climes, the mallee eucalypt vegetation is found on the calcareous soils of the south, and a variety of other vegetation structures are found in the vast arid zone and in the alpine, coastal, and wetland landscapes of the continent.

Most families and many genera now found in the Australian flora developed over 100 million years ago, before the Gondwanan supercontinent began to break up. Vast expanses

of infertile lateritic soils developed in the subtropical and tropical climates of that time (Prescott and Pendleton, 1952; Specht and Specht, 1999). Subtropical and tropical rainforests were widespread, with cool temperate *Nothofagus* forests at higher altitudes (Specht, 1981b; Specht *et al.*, 1992). Gondwanan and Old World Tropical C4 grasses (67 genera, including two species), were widespread at the lateritic earths of tropical Australia and extended southwards on medium-nutrient soils far to the south (Clifford and Simon, 1981). Many woody plant species on the sandstone outcrops of northern Australia are identical with those found on the sandstone hills of western Bengal and central India (Hooker, 1860; Specht, 1958; Specht, 1981a; Specht, 1988a). In the south of the continent, sclerophyllous (heathy) vegetation ($\pm$ an overstory of *Eucalyptus* spp.) flourished on sandstone and quartzitic outcrops and formed wet-heathlands with species of Restionaceae and Cyperaceae on sandy out-wash plains (Johnson and Briggs, 1981; Specht *et al.*, 1992). Today, most of the Australian *Acacia* species, widespread across the continent, belong to the subgenus *Racosperma*; five *Acacia* species, related to the Gondwanan parent genus of *Acacia* in South America, Africa, and India, still survive in northern Australia (Specht 1981a).

The genus *Eucalyptus* (Myrtaceae) appears to have evolved in the Early Tertiary across the southern part of the continent, the earliest pollen appearing in the Oligocene about 34 million years ago, extending from New Zealand in the east to the Ninety-East Ridge in the west (Martin, 1981; Pole, 1989; Pole, 1993). The fossil fruits of *Eucalyptus patagonica*, found in Eocene deposits in South America (Hill, 1994 and Hill, 2004), however, suggest that Australasian eucalypts may have evolved long before, in Gondwanaland. Some of the fossil pollen grains of the Early Tertiary resemble those of *E. spathulata* (in the subgenus *Symphyomyrtus*), now a stunted mallee species

growing in south-west Western Australia (Martin and Gadek, 1988). Fossil leaf impressions indicate that tropical *Corymbia* (bloodwoods and spotted gums), until recently considered a subgenus of *Eucalyptus*, evolved at the periphery of the rain-forests, even as far south as Tasmania (Ladiges *et al.*, 2003).

The onset of aridity during the Cainozoic (Martin, 2006), especially when global temperatures rose by about 5 °C during the Mid-Miocene (Feary *et al.*, 1991; Shackleton and Kennett, 1975), caused fragmentation of the humid/perhumid Gondwanan vegetation. Less humid elements in the flora began to expand and evolve, eventually to cover much of the continent. In the drier center of the continent, extensive stands of a tall shrubland of mulga (*Acacia aneura*) were mixed with hummock grasslands dominated by the spiny spinifex grass, *Triodia basedowii*, on low-nutrient soils (Specht and Specht, 1999). Chenopod low shrublands (with stands of *Casuarina pauper*) occupied the Early Miocene calcareous soils in the south of the continent (Specht and Specht, 1999).

The vegetation of Australia today comprises those taxa that were able to survive as the evaporative climate became drier. A distinctive heathy understory has survived on the nutrient-poor lateritic podzols, also on quartzitic/sandstone and acid granitic rocks, characteristic of a large part of the original Gondwanan super-continent. A savanna understory of Gondwanan C4 grasses survived under eucalypt open-forests and woodlands on medium-nutrient lateritic earth. The attributes that enabled most of the Gondwanan flora to survive over the last 50 million years also facilitates their rapid regeneration from underground organs and epicormic buds whenever a disturbance such as a fire occurs.

Evaporative Aerodynamics

Water – its availability through annual and supra-annual cycles, and the aridity of the atmosphere prevalent over most of the continent – is the primary limiting factor in ecosystem development in the Australian continent. The distribution of foliage in the overstory and understory canopies, and the eco-physiological attributes of the foliage (such as the “sclerophylly” characteristic of much Australian vegetation) is primarily governed by water availability in relation to atmospheric demand. The growth of new shoot apices (in both overstory and understory strata) is in equilibrium with the evaporative aerodynamics of the atmosphere flowing over and through the plant community (Specht, 1972; Specht and Specht, 1999). The amount of available water affects the vertical growth of each foliage shoot (and the number of essentially identical leaves produced annually), but not the horizontal cover of the foliage throughout the plant community, (Specht and Specht, 1989a) which is determined by evaporative demand, a relatively constant factor from year to year.

After any perturbation, the horizontal cover of the foliage and its eco-physiological characteristics are rapidly restored in both the overstory and understory of an evergreen plant community. The ratio of actual to potential evapotranspiration (per hectare) from the plant community is linearly related to the amount of water available during each month; the slope of this linear regression is called the Evaporative Coefficient

(Specht, 1972). Values of this community–physiological constant have been computed for meteorological stations throughout Australia and the resulting isolines are mapped in Figure 1.

Major Plant Communities in Australia

Plant communities are fundamental to ecosystem definition. The great number of tree species (20–140) that coexist in subtropical and tropical plant communities in Australia, from the arid to the perhumid evaporative zones, however, makes the definition of statistically “homogeneous” suites within the vegetation a challenge. This is not faced by temperate plant ecologists who deal with simple systems with relatively low numbers of overstory species per hectare (1–10 in number). The polythetic-divisive classificatory program TWINSpan (Hill, 1973) was used to assist the objective identification of plant communities, henceforth called TWINSpan floristic groups.

TWINSpan floristic groups were defined in the 29 Australian plant formations (Specht *et al.*, 1995). To accomplish this, complete species lists (several floristic lists could not be included) reported for plant communities throughout the continent since the 1890s were collated and arranged according to structural formation (Table 1). These were collated into 16 large data banks and were analyzed using TWINSpan by the CSIRO Division of Computing Research based on the presence or absence of a species in each list.

In each case, the communities were first sorted by the program according to climatic zone, emphasizing the importance of climate to species occurrence. First, the tropical/subtropical plant communities in northern Australia were separated from the temperate/montane plant communities in southern Australia. Then the tropical communities were separated from the subtropical, and the temperate from the montane. Further subdivision separated the humid plant communities from the subhumid, and so on for plant communities that had developed in different microenvironments. The number of TWINSpan floristic groups and their subdivisions that were recorded in each 30' latitude by 30' longitude grid-cell are shown in the *Conservation Atlas of Plant Communities in Australia* (Specht *et al.*, 1995). The diversity of floristic groups is greatest in the perhumid zone, and least in the arid evaporative zone.

TWINSpan analysis resulted in the definition of 338 overstory floristic groups. A further 60 understory floristic groups were recognized in open-structured plant communities (Specht *et al.*, 1995).

Diagnostic Species in Australian Floristic Groups

The plant species, which define the floristic groups (Specht *et al.*, 1995) determined by TWINSpan in the 29 Australian plant formations (Table 1) are listed below. Each floristic group has been given a code: capital letters for the formation (e.g., RF = closed-forest (rainforest), T = open-forest and woodland), followed by numerals. The numerals refer to the dichotomous

Figure 1 Map of Australia showing isolines of the Evaporative coefficient (k). Climatic zones may be defined as follows: Arid zone, $k < 0.35$; semi-arid zone, $k \equiv 0.35\text{--}0.45$; subhumid zone, $k \equiv 0.45\text{--}0.55$; humid zone, $k \equiv 0.55\text{--}0.75$; perhumid zone, $k > 0.75$. (All values of k are $\times 10^{-2}$ per mm of soil water available per month.) (Specht, 1972; Specht and Specht, 2002).

subdivisions in the TWINSPLAN classification; within a formation, groups having consecutive odd–even pairs of numerals are most closely related (e.g., RF35 and RF36). In species-rich formations, such as closed-forests, subdivisions of the primary TWINSPLAN groups are shown by the numbers in parentheses.

Closed-forests (rainforests) – tropical north-eastern Australia (Webb *et al.*, 1984)

- RF42(170) *Nothofagus moorei* – *Tristaniaopsis laurina*
- RF42(171) *Doryphora sassafras*
- RF43(86) *Acmena smithii* – *Ficus coronata* – *Eupomatia laurina*

Table 1 Structural characteristics of major plant formations in Australia^a

Formation	Climatic zone	Overstory			Understory
		Stand height (m)	Foliage projective cover (%)	Leaf-specific-weight ^b (mg cm ⁻²)	
Overstory with trees					
Closed-forest	Perhumid	20 ^c –10	100–70	8–16	Regeneration saplings, shade-tolerant plants
Open-forest	Humid	> 30–10	70–30	10–28	Grassy, heathy
Woodland	Subhumid	20–10	30–10	13–40	Grassy, heathy
Open-scrub	Semiarid	5–2	70–30	18–50	Grassy, heathy
Tall shrubland	Arid	5–2	30–10	20–> 50	Grassy, hummock grass, chenopods
Treeless vegetation					
Heathland	Humid–subhumid	2–0.25	70–30	Sclerophyllous	–
Dwarf heathland (fellfield)	Montane	< 0.25	30–< 10	Sclerophyllous	–
Tussock grassland	Humid–subhumid	1–0.25	70–30	Herbaceous	–
Open tussock grassland	Semiarid	< 0.25	30–10	Herbaceous	–
Hummock grassland	Semiarid–arid	1–0.5	70–10	Sclerophyllous	–

^aBased on Specht *et al.* (1995) and Specht and Specht (2002).^bLeaf/leaflet area decreases and leaf specific weight increases in the 10 °C temperature gradient from tropical to temperate regions.^cIn the tropics and subtropics, there are emergent trees and strangler figs, lianas and epiphytes.

RF43(87) *Acacia melanoxylon* – *Acmena smithii*
 RF44(88) *Cryptocarya floydii* – *Pittosporum undulatum*
 RF44(178) *Podocarpus elatus* – *Syzygium oleosum*
 RF44(359) *Araucaria cunninghamii* – *Flindersia australis*
 RF44(358) *Araucaria cunninghamii* – *Argyrodendron trifoliolatum* – *Drypetes* sp.
 RF45(180) *Araucaria cunninghamii* – *Argyrodendron trifoliolatum* – *Cryptocarya bidwillii*
 RF45(181) *Murraya ovatifoliolata*
 RF45(182) *Araucaria cunninghamii* – *Austromyrtus bidwillii*
 RF45(183) *Strychnos axillaris*
 RF46(93) *Apophyllum anomalum* – *Maytenus cunninghamii*
 RF46(184) *Cupaniopsis anacardioides* – *Pleiogynium timorense*
 RF46(185) *Casearia multinervosa* – *Croton insularis*
Closed-forests (rainforests) – temperate south-eastern Australia (Webb *et al.*, 1984)
 RF7 *Nothofagus cunninghamii* – *Athrotaxis cupressoides* – *Diselma archeri*
 RF13 *Nothofagus cunninghamii* – *Atherosperma moschatum*
 RF24 *Nothofagus cunninghamii* – *Pittosporum bicolor*
 RF25 *Atherosperma moschatum* – *Pittosporum bicolor*
Semi-deciduous closed-forests – monsoonal northern Australia (Russell-Smith, 1991)
 MRF1 *Aglaia sapidina* – *Hydriastele wendlandiana*
 MRF2 *Acacia auriculiformis* – *Carpentaria acuminata*
 MRF3 *Acmenosperma claviflorum* – *Macaranga involucreta*
 MRF4 *Calophyllum sil* – *Ficus hispida* – *Ilex arnhemensis*
 RF34(69) *Carallia brachiata* – *Ilex arnhemensis*
 MRF5 *Acmenosperma claviflorum* – *Litsea breviumbellata*
 MRF6 *Omalanthus novo-guineensis* – *Xanthostemon eucalyptoides*
 MRF7 *Allosyncarpia ternata* – *Calophyllum sil*
 MRF8 *Allosyncarpia ternata* – *Alyxia ruscifolia*
 MRF9 *Aglaia rufa* – *Diospyros maritima* – *Secamone elliptica*

MRF10 *Barringtonia acutangula* – *Livistona benthamii*
 MRF11 *Ficus racemosa* – *Melaleuca argentea*
 MRF12a *Canarium australianum* – *Celtis philippensis*
 MRF12b *Alstonia spectabilis* – *Denhamia obscura*
 MRF13 *Ficus coronulata* – *F. virens* – *Glochidion apodogynum*
 MRF14 *Brachychiton collinus* – *Callicarpa candicans*
 MRF15 *Brachychiton spectabilis* – *Ziziphus quadrilocularis*
 RF47 *Brachychiton chillagoensis* – *Terminalia aridicola*
 RF16(132) *Gyrocarpus americanus* – *Lysiphyllum cunninghamii*
 RF16(32) *Ficus platypoda* var. *minor*
Semi-deciduous closed-forests – subtropical eastern Australia (Forster *et al.*, 1991)
 DS8(16) *Cupaniopsis parvifolia* – *Diospyros humilis* – *Owenia venosa*
 DS8(17) *Cupaniopsis parvifolia* – *Maclura cochinchinensis*
 DS9(18) *Archidendropsis thozetiana* – *Cupaniopsis wadsworthii*
 DS9(19) *Archidendropsis thozetiana* – *Brachychiton rupestris*
 DS10(20) *Pleiogynium timorense* – *Pouteria sericea*
 DS10(21) *Alchornea ilicifolia* – *Cryptocarya triplinervis*
 DS11(22) *Cupaniopsis parvifolia*
 DS11(23) *Cupaniopsis parvifolia* – *Araucaria cunninghamii*
 DS12(24) *Mischocarpus pyriformis* – *Alyxia ruscifolia*
 DS12(25) *Mischocarpus pyriformis* – *Araucaria cunninghamii*
 DS13(26) *Araucaria cunninghamii* – *Alectryon tomentosus* – *Cleistanthus cunninghamii*
 DS13(27) *Araucaria cunninghamii* – *Alectryon tomentosus* – *A. subcinereus*
 DS14(28) *Cryptocarya macdonaldii* – *C. laevigata*
 DS14(29) *Cryptocarya macdonaldii*
 DS15(30) *Araucaria cunninghamii* – *Calamus muelleri* – *Wilkiea macrophylla*
 DS15(31) *Araucaria cunninghamii* – *Maclura cochinchinensis* – *Smilax australis*

DS40 *Alectryon forsythii* – *A. subdentatus* – *Notelaea microcarpa*
Eucalypt open-forests and woodlands – monsoonal northern Australia (R. L. Specht and D. W. Drake, unpublished data)

T187a *Eucalyptus leucophloia*

T189 *Eucalyptus microneura*

T359 *Eucalyptus brownii* – *E. crebra*

T361 *Eucalyptus chloroclada* – *E. sideroxylon*

T362 *Eucalyptus microcarpa*

T363a *Eucalyptus microcarpa* – *E. populnea*

T364 *Eucalyptus populnea* – *E. orgadophila*

T365 *Eucalyptus melanophloia*

Calcolu *Callitris glaucophylla*

Serp-R *Eucalyptus fibrosa* subsp. nov. *Corymbia xanthope* – *Macrozamia* sp. nov.

Serp-W *Eucalyptus crebra* – *Corymbia erythrophloia* – *Macrozamia* sp. nov.

Serp-B *Eucalyptus ophitica* – *Xanthorrhoea glauca*

T706 *Eucalyptus pilularis* – *Corymbia gummifera* – *Angophora* spp.

T707 *Eucalyptus paniculata* – *E. propinqua*

T710 *Euc. acmenoides* – *E. pilularis* – *E. microcorys* – *Syncarpia glomulifera*

T710b *Eucalyptus grandis*

Eucbiturb *Eucalyptus biturbinata*

Eucclae *Eucalyptus cloeziana* – *E. tenuipes*

Shill *Syncarpia hillii*

T711 *Eucalyptus signata* – *Corymbia intermedia*

T712 *Eucalyptus crebra* – *Corymbia citriodora* – *C. trachyphloia*

T713 *Corymbia intermedia* – *Lophostemon* spp.

T714 *Eucalyptus tereticornis* – *Lophostemon suaveolens*

T715 *Eucalyptus tereticornis* – *Corymbia tessellaris* – *C. clarksoniana*

T716a *Eucalyptus crebra* – *E. tereticornis* – *Corymbia maculata*

T716b *Eucalyptus moluccana* – *E. tereticornis*

T717 *Eucalyptus crebra* – *Corymbia maculata*

Eucalypt open-forests and woodlands – temperate south-eastern Australia (R. L. Specht and D. W. Drake, unpublished data)

T172 *Eucalyptus regnans*

T328a *Eucalyptus odorata* – *E. porosa*

T329 *Eucalyptus leucoxylon*

T330 *Eucalyptus fasciculosa* – *E. leucoxylon*

T331 *Eucalyptus baxteri* – *E. fasciculosa*

Eucpryor *Eucalyptus pryoriana* – *E. viminalis* subsp. *cygnetensis*

Eucnit *Eucalyptus nitida*

T338 *Eucalyptus albens* – *E. blakelyi* – *E. melliodora*

T339 *Eucalyptus dealbata* – *E. blakelyi* – *E. sideroxylon*

T340 *Eucalyptus blaxlandii* – *E. goniocalyx*

T341 *Eucalyptus macrorhyncha* – *E. polyanthemus*

T342 *Eucalyptus dives* – *E. macrorhyncha* – *E. radiata*

T347 *Eucalyptus cypellocarpa* – *E. obliqua* – *E. radiata*

T348 *Eucalyptus globoidea* – *E. sieberi*

T349 *Eucalyptus globoidea* – *Corymbia gummifera*

T350 *Eucalyptus piperita* – *E. sieberi*–*Corymbia gummifera*

T40 *Eucalyptus cordata*

T664 *Eucalyptus nitida*

T665 *Eucalyptus cephalocarpa* – *E. globoidea*

T666 *Eucalyptus viminalis*

T667 *Eucalyptus obliqua*

Eucalypt open-forests and woodlands – montane south-eastern Australia (R. L. Specht and D. W. Drake, unpublished data)

T8 *Eucalyptus coccifera*

T36 *Eucalyptus obliqua* – *E. amygdalina* – *E. globulus*

T38 *Eucalyptus delegatensis* – *E. dalrympleana* – *E. viminalis*

T75 *Eucalyptus urnigera* – *E. delegatensis*

T79 *Eucalyptus brookeriana* – *E. delegatensis*

T148 *Eucalyptus obliqua*

T149 *Eucalyptus delegatensis* – *E. regnans* – *E. obliqua*

T156 *Eucalyptus delegatensis* – *E. pauciflora* – *E. rubida*

T157 *Eucalyptus delegatensis* – *E. pauciflora* – *E. rodwayi*

T334 *Eucalyptus pauciflora* – *E. rubida*

T335 *Eucalyptus pauciflora* – *E. stellulata*

Eucalypt open-forests and woodlands – temperate south-western Australia (R. L. Specht and A. J. M. Hopkins, unpublished data)

SW20 *Eucalyptus gomphocephala* – *Agonis flexuosa*

SW26 *Eucalyptus loxophleba*

SW43a *Eucalyptus marginata* – *Corymbia calophylla*

SW47 *Eucalyptus marginata* – *Banksia* spp. – *Allocasuarina humilis*

SW85 *Eucalyptus diversicolor*

SW96a *Eucalyptus wandoo*

SW97a *Eucalyptus salmonophloia*

SW100 *Eucalyptus loxophleba* – *E. salmonophloia*

Eucalypt open-forests and woodlands – Australian wetland forests (Specht, 1990)

T188 *Eucalyptus coolabah*, *E. microtheca*, etc.

T191 *Eucalyptus ochrophloia* – *E. coolabah*

T190 *Eucalyptus camaldulensis*

T352b *Casuarina cunninghamiana*

T354 *Melaleuca quinquenervia* – *Eucalyptus robusta*

T366a *Eucalyptus largiflorens*

T366b *Allocasuarina luehmannii*

T370 *Eucalyptus leptophleba*

SW4a *Eucalyptus rudis* – *Melaleuca raphiophylla*

SW4b *Eucalyptus rudis* – *Corymbia calophylla*

SW84 *Agonis hypericifolia* – *Banksia littoralis*

T801 *Melaleuca leucadendra* – *M. viridiflora*

Mallee eucalypt open-scrubs – monsoonal northern Australia (R. L. Specht, unpublished data)

¹*Corymbia* was formerly regarded as a subgenus of *Eucalyptus*.

Euccupu *Eucalyptus cupularis*
 Eucmann *Eucalyptus mannensis*
 Eucnorm *Eucalyptus normantonensis*
 Eucpers *Eucalyptus persistens*
 Eucoxym *Eucalyptus oxymitra*
 Eucpach *Eucalyptus pachyphylla*
 Eucset *Corymbia setosa*
 Eucthoz *Eucalyptus thozetiana* – *Acacia catenulata* – *A. aneura*
Mallee eucalypt open-scrubs – subtropical eastern Australia
 (R. L. Specht, unpublished data)
 Eucappr *Eucalyptus approximans*
 Eucbake *Eucalyptus bakeri*
 Euccurr *Eucalyptus curtisii*
 Serp-GW *Eucalyptus serpenticola* – *E. nortonii* – *Allocasuarina ophiolitica*
Mallee eucalypt open-scrubs – temperate south-eastern Australia
 (R. L. Specht, unpublished data)
 M7 *Eucalyptus diversifolia* – *E. cosmophylla* – *E. rugosa* – *Melaleuca uncinata*
 M10 *Eucalyptus behriana*
 M13 *Eucalyptus diversifolia* – *E. socialis*
 M23 *Eucalyptus socialis* – *E. dumosa* – *E. gracilis* – *E. polybractea*
 M24 *Eucalyptus incrassata* – *E. viridis* – *E. polybractea*
 M25 *Eucalyptus incrassata* – *E. foecunda* – *Melaleuca uncinata*
 M4 *Eucalyptus socialis* – *E. dumosa*
 M44 *Eucalyptus socialis* – *E. dumosa* – *E. gracilis* – *Acacia rigens*
 M45 *Eucalyptus socialis* – *E. dumosa* – *E. gracilis* – *Enchylaena tomentosa*
 Eucinte *Eucalyptus intertexta* – *Callitris glaucophylla*
 Euckits *Eucalyptus kitsoniana*
 Eucobtus *Eucalyptus obstans* – *E. luehmanniana*
Mallee eucalypt open-scrubs – temperate south-western Australia
 (R. L. Specht and A. J. M. Hopkins, unpublished data)
 SW27 *Eucalyptus diversifolia* – *E. oleosa* – *Melaleuca lanceolata*
 SW51 *Eucalyptus leptopoda* – *Callitris preissii* – *Melaleuca cordata*
 SW101b *Eucalyptus eremophila* – *E. forrestiana* – *E. oleosa*
 SW196 *Allocasuarina campestris*
 SW197 *Allocasuarina campestris* – *Acacia acuminata* – *Eucalyptus obtusiflora*
Heathlands and related shrublands – monsoonal northern Australia
 (R. L. Specht and W. E. Drake, unpublished data)

 H82 *Melaleuca nodosa* – *Gahnia sieberana* – *Blechnum indicum*
 H166 *Leptospermum polygalifolium* – *Phyllota phyllicoides*
 H167 *Leptospermum polygalifolium* – *Platysace linearifolia*
 Xanth *Xanthorrhoea* spp.
Heathlands and related shrublands – temperate south-eastern Australia
 (R. L. Specht and W. E. Drake, unpublished data)
 H44a *Melaleuca uncinata*

H44b *Banksia ornata* – *Xanthorrhoea caespitosa* – *Allocasuarina pusilla*
 H45 *Melaleuca uncinata* – *Xanthorrhoea semiplana* var. *tateana*
 H84 *Banksia ericifolia* – *Hakea dactyloides*
 H170 *Banksia marginata* – *Epacris impressa*
 H171 *Banksia marginata* – *Epacris impressa* – *Pteridium esculentum*
Heathlands and related shrublands – montane south-eastern Australia
 (Kirkpatrick, 1989)
 AV1 *Carex gaudichaudiana* – *Myriophyllum pedunculatum*
 AV2 *Carex gaudichaudiana*
 AV3 *Baeckea gunniana* – *Epacris breviflora* – *Carex gaudichaudiana*
 AV4 *Baeckea gunniana* – *Epacris paludosa* – *E. lanuginosa*
 AV5 *Oxylobium alpestre* – *Olearia phlogopappa* – *Phebalium ovatifolium*
 AV6 *Grevillea australis* – *Epacris paludosa* – *Poa* spp.
 AV7 *Leucopogon montanus* – *Poa* spp.
 AV8 *Podocarpus lawrencei*
 AV9 *Microtrobos niphophilus* – *Epacris serpyllifolia*
 AV10 *Abrotanella forsterioides* – *Richea scoparia*
 AV11 *Carpha rodwayi* – *Oreobolus pumilio* – *Phyllachne colensoi*
 AV12 *Diselma archeri* – *Microcachrys tetragona*
 AV13 *Gaultheria depressa* – *Senecio leptocarpus*
 AV14 *Epacris serpyllifolia* – *Orites revoluta* – *Richea sprengelioides*
 AV15 *Epacris serpyllifolia* – *Richea scoparia* – *Senecio leptocarpus*
 AV16 *Eucalyptus vernicosa* – *Nothofagus cunninghamii*
 AV-Ngum *Nothofagus gunnii*
Heathlands and related shrublands – temperate south-western Australia
 (George *et al.*, 1979; R. L. Specht and A. J. M. Hopkins, unpublished data)
 SW22 *Allocasuarina humilis* – *Calothamnus quadrifidus* – *Dryandra nivea*
 SW46 *Allocasuarina humilis* – *Dryandra nivea* – *Hakea lissocarpa*
 SW47b *Banksia attenuata* – *B. menziesii*
 SW99a *Allocasuarina acutivalvis*
Tussock grasslands
 (R. L. Specht and M. P. Bolton, unpublished data)
 G8 *Astrelba elymoides* – *Iseilema membranaceum*
 G11 *Dichanthium sericeum*
 G18 *Astrelba* spp. – *Dichanthium fecundum* – *Iseilema* spp.
 G19 *Astrelba elymoides* – *A. lappacea*
 G56 *Xerochloa* spp. – *Eleocharis* spp. – *Oryza sativa*
 G69 *Themeda triandra* (Basalt Plains, western Victoria)
 G114 *Themeda triandra* (coastal headlands, Queensland)
 GDanth *Danthonia caespitosa*
Acacia vegetation – subhumid, subtropical eastern Australia
 (R. L. Specht, M. P. Bolton, and A. Specht, unpublished data)
 HW11 *Acacia harpophylla* – *Casuarina cristata*
 DA8a *Acacia catenulata*
 DA8b *Acacia shirleyi*
 DA18 *Acacia cambagei*
 DA40 *Acacia pendula* – *Atriplex nummularia*
 DAargy *Acacia argyrodendron*
 DAspar *Acacia sparsiflora* – *A. burrowii*
 DAsuth *Acacia sutherlandii* – *Astrelba* spp.
Acacia vegetation – Australian Arid Zone
 (R. L. Specht, M. P. Bolton, and A. Specht, unpublished data)
 DA14a *Acacia ligulata*

DA19 *Acacia aneura* – *Eucalyptus populnea* – *Eremophila mitchellii*
 DA21 *Eucalyptus terminalis* – *Acacia ligulata* – *A. dictyophleba*
 DA22a *Acacia aneura* – *Senna* spp. – *Eremophila* spp.
 DA22d *Acacia sclerosperma* – *A. aneura*, etc.
 DA24 *Eucalyptus terminalis* – *Acacia dictyophleba* – *Senna artemisioides*
 DAgeor *Acacia georginae*
 DA41a *Acacia aneura* – *Alectryon oleifolius*
 C24 *Acacia papyrocarpa* – *Maireana sedifolia*
 DA46a *Acacia kempeana* – *A. aneura*
 DA47 *Acacia acradenia* – *A. tenuissima* – *Senna artemisioides*
 DA51 *Eucalyptus gamophylla* – *Acacia* spp. – *Dodonaea viscosa*
 DA62 *Eucalyptus kingsmillii* – *E. youngiana* – *E. gamophylla* – *Triodia* sp.
 DA62a *Eucalyptus gongylocarpa* – *Triodia basedowii*
 DA63a *Eucalyptus gamophylla* – *Acacia* spp. – *Thryptomene maisonneuvei*
 DA100g *Eucalyptus dichromophloia* – *Acacia lysiphloia* – *Acacia* spp.
 DA101c *Acacia pachycarpa* – *Eucalyptus dichromophloia*
 Casdec *Allocasuarina decaisneana* – *Triodia basedowii*
 DAstow *Acacia stowardii* – *Senna* spp. – *Eremophila* spp.
 Erem *Eremophila* spp. – *Dodonaea* spp. – *Senna* spp. – *Acacia* spp.
Hummock grasslands – Australian Arid Zone (R. L. Specht and E. E. Hegarty, unpublished data)
 HG1 *Triodia pungens*
 HG2 *Triodia basedowii*
 HG3 *Triodia wiseana*
 HG4 *Triodia intermedia* – *Eriachne obtusa*
 HG5 *Triodia inutitilis* – *Triodia* spp.
 HG6 *Plectrachne schinzii*
 HG7 *Triodia clelandii* – *T. irritans*
 HG8 *Triodia basedowii* – *Zygochloa paradoxa*
 HG9 *Triodia irritans*
 HG10 *Triodia hubbardii*
Chenopod low shrublands – southern Australian Arid Zone (R. L. Specht and A. Specht, unpublished data)
 C4 *Atriplex vesicaria* – *Maireana sedifolia*
 C7 *Myoporum platycarpum* – *Atriplex vesicaria* ± *Cratystylis* sp.
 C13 *Alectryon oleifolius* ± *Atriplex vesicaria* ± *Maireana* spp.
 C20 *Halosarcia* spp. (inland salt marsh)
 C21 *Atriplex vesicaria* – *Maireana aphylla* – *M. planifolia*
 C22 *Casuarina pauper* – *Maireana pyramidata*
 C23a *Atriplex vesicaria* – *A. nummularia* – *Acacia pendula*
 C24 *Acacia papyrocarpa* – *Maireana sedifolia*
Aquatic vegetation – tropical and subtropical northern Australia (R. L. Specht and M. P. Bolton, unpublished data)
 A12 *Monochoria cyanea* – *Potamogeton tricaratus*
 A15/26 *Caldesia oligococca* – *Eleocharis dulcis* – *Nymphaea gigantea*
 A27 *Caldesia oligococca* – *Nymphaea gigantea*
 A28 *Typha domingensis* – *Caldesia oligococca*
 A29 *Typha domingensis*
 Restio *Leptocarpus spathaceus* – *Restio tetraphyllus*
Aquatic vegetation – temperate southern Australia (Aston, 1973; R. L. Specht and M. P. Bolton, unpublished data)
 A16 *Eleocharis acuta* – *Isolepis fluitans* – *Lepilaena* spp.
 A17 *Lemna minor* – *Isoetes muelleri*

A18/19 *Eleocharis acuta* – *E. sphacelata*
 A22 *Eleocharis acuta* – *E. sphacelata* – *Typha* spp. – *Maundia* sp.

Biogeographic Regions in Australia

The presence or absence of TWINSPLAN floristic groups in each 1° latitude by 1° longitude grid-cell of the Australian continent was analyzed using the agglomerative classification program, PATN (Belbin, 1989). The symmetric form of the Kulczynski measure with $\beta \equiv -0.1$ was used to determine the association between community groups in each grid cell. This has been found to produce the most useful classification for such ecological applications (Faith *et al.*, 1987) and in this case produced the most “sensible” results. The results are plotted as a dendrogram in Figure 2. The resulting distribution of the

Figure 2 Dendrogram showing the relationships of the biogeographic regions of Australia derived from a Kulczynski symmetric pattern analysis of the major TWINSpan floristic groups recorded in 1° latitude by 1° longitude grid-cells throughout Australia (Specht and Specht, 2002).

biogeographic regions identified by the foregoing analysis is plotted in **Figure 3**.

The first subdivision of the Kulczynski Symmetric dendrogram (**Figure 2**) separated the arid and semi-arid biogeographic regions of Western Australia, Northern Territory, South Australia, and north-western Victoria. Three biogeographic regions (AN2–4) were defined in the northern section of the arid zone, an area that receives mostly summer rainfall. The biogeographic regions of Central Australia (AC) and the Ashburton (ANI) of Western Australia receive both summer and winter rainfall. Although summer rains occur erratically, winter rainfall is predominant in the southern arid zone (A1a–b, A2a–b, A3, A4a–b) and in the semi-arid climatic zone (SW1–2 and S1–3). The TWINSpan floristic groups on the mid-tertiary limestone sediments from the Nullarbor Plain

(A3) across South Australia (S1 and S2) into north-western Victoria (S3) are closely related.

The complex of TWINSpan floristic groups (A1a–b) in the southern section of the arid zone of Western Australia are closely interrelated (and probably should not be separated); they are affiliated with the vegetation of the Ashburton region (AN1), where summer rainfall predominates. The northern section (A2a–b) of the arid zone in South Australia is distinctly separated from the southern arid vegetation (A4a–b) in which outliers of the mallee open-scrub (dominant in the semi-arid climate of S1–3) are to be found.

The second subdivision of the Kulczynski Symmetric dendrogram differentiated both the vegetation of the humid/per-humid section of south-western Australia (SW1–2, with a Mediterranean-type climate) and all the biogeographic regions in eastern Australia (where rainfall is evenly distributed throughout the year). Biogeographic regions were defined in the humid/perhumid climates of Tasmania to south-eastern Queensland (T, Tasmania; SV, Southern Victoria; and E1–3, Eastern Australia). Subhumid biogeographic regions were defined in central Queensland (CQ1–3) and in central New South Wales (CN), with related biogeographic regions (BT, the Barkly Tableland; CC, the Channel Country; and A5, Far Western New South Wales) in the semi-arid to arid zones of both states.

The third subdivision of the Kulczynski Symmetric dendrogram defined the biogeographic regions in northern Australia, where summer rainfall alternates with winter drought. The biogeographic regions of Cape York Peninsula (NE1) and the Gulf of Carpentaria (NE2) in Queensland are closely related to the wet tropical region (NE3) that extends southwards along the coast toward the tropic of Capricorn.

The TWINSpan floristic groups of the humid/subhumid section of the Kimberley (N3) and the Top End of the Northern Territory (N1–2) are interrelated and were differentiated from the inland, semi-arid/sub-humid biogeographic regions (N11–3) across northern Australia and the Hamersley Ranges (HR) in Western Australia.

Diagnostic Floristic Groups in Australian Biogeographic Regions

The TWINSpan groups associated with each of the biogeographic regions are shown below.

- N1 (humid north-western W.A.) – RF34(69), MRF12a, T371, T372.
- N2 (humid N.T.) – MRF12a, T187a, T371, T372, T373a, G56, H7.
- N3 (humid Cape York Peninsula and Gulf, Qld.) – RF35(140), RF35(141), T370, T372, T373a, G18, H12, H13.
- N4 (Broome-Derby, W.A.) – RF16(132), T372.
- N5 (southern Kimberley region, W.A.) – RF16(132), T187a, T371, T372.
- N6 (subhumid N.T.) – T187a, T371, T372, H7.
- N7 (semi-arid N.T.) – T187a, T372, DA8b.
- N8 (Pilbara region, W.A.) – T372, DA100g.
- NE1 (subhumid Cape York Peninsula, Qld.) – T188, T189, T368, T369, T371, T714, T801, G18.
- NE2 (perhumid north-eastern Qld.) – RF35(142), RF35(143), RF36(144), RF36(145), T368, T369, T371, T710, T712, T713, T714, T715, T801.

Figure 3 Biogeographic regions of Australia derived from a Kulczynski Symmetric Pattern Analysis of the major TWINSpan floristic groups recorded in 1° latitude by 1° longitude grid-cells throughout Australia (Specht *et al.*, 1995).

NE3 (subhumid north-central highlands, Qld.) – T188, T189, T368, T369, T714, DA8b.

NE4 (subhumid central Qld.) – RF46(184), T188, T364, T352b, T365, T369, T714, T716a, T717, HW11, DA8a.

NE5 (subhumid south-eastern Qld.) – T188, T360, T363a, T364, T365, T369, T716a, T717, Calcolu, HW11.

BT (Barkly Tableland, Qld.) – T188, G8, G19.

CC (Channel Country, Qld.) – T188, DA18, DA19, C20.

SE1 (humid south-eastern Qld.) – RF45(180), RF41(332), T354, T707, T710, T711, T713, T714, T715, T716a, T717, G11, H82, H166, H167.

SE2 (perhumid Border Ranges, N.S.W.–Qld.) – RF42(169), RF40(322), RF40(325), T346, T707, T710, H82, H84, H166, H167.

SE3 (central to northern coasts and highlands, N.S.W.) – T334, T347, T350, T354, T707, T710, T716b, H82, H84, H166, H167.

SE4 (south-eastern and montane N.S.W.–Vic.) – RF25, T38, T79, T156, T157, T334, T335, T347, T348, T349, T350, AV4, AV6, H84.

SE5 (south-western to south-eastern Vic.) – RF24, T331, Eucpryor, T341, T342, T666, T667, G69, H170, H171.

SE6 (Tasmania) – RF7, RF13, T8, T36, T40, T148, T149, Eucnit, T666, T667, AV14, AV15, H170, H171.

SE7 (northern tablelands, N.S.W.) – T338, T339, T362, T363a, T717, Calcolu.

SE8 (southern and central tablelands, N.S.W.) – T190, T338, T339, T341, T362, T363a, T716b, Calcolu.

SE9 (humid Mt. Lofty Ranges and South East District, S.A.) – T190, T328a, T329, T330, T331, T667, H170.

S1 (Nullarbor Plain, S.A.) – M13, M45, C4, C20.

S2 (northern Eyre and Yorke Peninsulas, S.A.) – M25, M45, C24, DA14a, H44b.

S3 (subhumid S.A.) – T190, T328a, T329, T330, T331, T366a, T366b, T667, M13, M25, H44b, H170.

S4 (north-western Vic.) – T190, T329, T362, T366a, T366b, M10, M25, M45, H44a, H44b.

SW1 (humid to perhumid south-western W.A.) – SW4a, SW20, SW43a, SW47, SW84, SW85.

SW2 (subhumid to semi-arid south-western W.A.) – SW22, SW46, SW96a, SW97a, SW100, SW196.

A1a (south-eastern Pilbara District, W.A.) – C20, DA14a, DA22a, DA51, DA62, DA63a.

A1b (southern part of Murchison District to Great Victoria Desert, W.A.) – C20, DA22a, DA62, SW197.

A1c (northern part of Murchison District to Great Victoria Desert, W.A.) – C20, DA22a, DA62, DA63a.

A1d (southern N.T.) – C20, DA21, DA46a.

A1e (Great Victoria Desert, S.A.) – C20, C22, DA62.

A2a (Great Sandy Desert, W.A.) – C20, DA100g, DA101c, HG6.

A2b (Tanami Desert, N.T.) – C20, DA47, HG6.

A3a (northern S.A.) – C20, DA21, DA41a, DA46a.

A3b (Simpson Desert, S.A.) – C20, HG2, HG8.

A4a1 (Exmouth Gulf, W.A.) – C20, DA14a.

Figure 4 (a) The number of TWINSpan floristic groups plotted against the number of principal soil types (Northcote *et al.*, 1960–1968) found in the same grid-cell of 1° latitude by 1° longitude dimensions in eastern and southern Australia (South-eastern Australian floristic groups = $1.34 \text{ soil groups} + 3.83$, $n=15$, $r^2=0.96$) and on the nutrient-poor soils of northern, central, and western Australia (Western Australian floristic groups = $0.92 \text{ soil groups} + 1.51$, $n=15$, $r^2=0.95$). (Specht and Specht, 2002; Specht and Tyler, 2010). (b) Number of marsupial species plotted against the number of TWINSpan floristic groups for the same area (number of species of marsupials = $0.37 + 0.99$ and number of floristic groups, $n=90$, $r^2=0.97$).

A4a2 (north-eastern Wheat Belt, W.A.) – C20, DA14a, SW100, SW196.

A4b (Goldfields, W.A.) – C20, DA14a, DA62, SW26, SW51, SW99a, SW101b.

A5a (Nullarbor Plain to Flinders Ranges, S.A.) – C4, C7, C13, C20, C21, C24, DA41a.

A5b (North East District, S.A.) – C4, C7, C13, C20, C22, DA41a, T366a.

A6 (western N.S.W.) – C4, C20, C22, C23a, DA41a, T366a.

Community Diversity of Australian Ecosystems

Over large areas, such as the 1° latitude by 1° longitude grid-cell, the diversity of habitats is high, resulting in a high diversity of TWINSpan floristic groups. This is illustrated by a positive correlation between the number of TWINSpan floristic groups in each grid cell and the number of soil types occurring within them (Figure 4(a)). This has influence on other biotic groups, illustrated by the positive relationship between the species richness of marsupials per unit area reported by Pianka and Schall (1981), and the gamma diversity of plant communities (Figure 4(b)).

Species Richness of Australian Ecosystems

Species richness of overstory and understory strata

The potential for annual foliage growth increases in the 10 °C temperature gradient from temperate to tropical Australia (Table 2). The numbers of both stems and species recorded in the overstory (per hectare) increases exponentially with

temperature zone and with moisture status (Table 2 and Figure 5(a)) (after Specht and Specht, 1993, 1994).

Photosynthesis in overstory leaves, and hence potential annual foliage growth, depends primarily on the amount of solar radiation incident on the plant community, this declining from tropical to temperate Australia. In the open-structured plant communities of the wet-dry tropics and subtropics, a high percentage of direct-beam solar radiation reaches the understory through the gaps in the overstory canopy; species richness (the number of species per hectare) can become higher than that of the exposed overstory and follows the exponential curve shown for the overstory (Figure 5(b)). In more temperate latitudes, solar radiation reaches the Earth at a lower angle, and consequently the amount of radiation that reaches the understory is low (Specht *et al.*, 1992; Specht and Specht, 1999), resulting in only a slight increase from the semi-arid to the perhumid zone, with the proportion of cryptogamic species substantial in the most humid climates.

On nutrient-poor soils, (residual lateritic podsoles, arenaceous, acid granitic, and serpentinitic soils, Quaternary sands, etc.) common in many parts of Australia, the species richness of the overstory is low, below that on higher-fertility soils in the same evaporative regime (Specht and Specht, 1989b). The species richness of the understory is positively related to solar radiation penetration as foliage cover in the overstory decreases (Figure 6).

Species Richness of Vertebrates and Invertebrates

The species richness of vertebrates recorded in a plant community is positively related to the species richness of vascular

Table 2 Structural characteristics of mature Australian plant communities^a

^aBased on Specht and Specht (1989a).^bStand heights of emergent eucalypts at the edge of rainforest stands.^cThe species richness of understories in perhumid to humid climates contains a mixture of regenerating overstory species as well as shadeloving vascular plants and cryptogams.

Figure 5 (a) Species richness (number of species per hectare) of the overstory increases exponentially as annual shoot growth of this stratum increases: $\ln N_s = 0.70 + 0.36 \text{ annual shoot growth}$ ($n = 12$, $r^2 = 0.98$). Species richness (N) increases exponentially (1) in the evaporative gradient from the arid zone (Evaporative coefficient $k < 0.35 \times 10^{-2}$) to the perhumid zone (Evaporative coefficient $k \approx 1.0 \times 10^{-2}$), and (2) in the 10°C temperature gradient from temperate to subtropical to tropical Australia (Specht and Specht, 1993). (b) The low amount of solar radiation that penetrates the overstory to reach the understory in the temperate latitudes of Australia has little effect on species richness (number of species per hectare) of this stratum. In the tropics and subtropics, however, the relationship of species richness of the understory to annual shoot growth (of the upper stratum) is similar to that shown by the overstory (Specht and Specht, 1993, 1994, 2002).

plants found in the understory stratum (Figure 7(a) and 7(b)), as indeed is the number of frog and snake species (Braithwaite *et al.*, 1985; P. C. Catling, in Specht, 1988b; Cody, 1994a and Cody, 1994b; Specht, 1994; Specht and Specht,

1999; Specht and Tyler, 2010). These may also be related to potential energy-fixation. An inverse correlation has been observed, however, for lizards, presumably reflecting their food and habitat preference.

It would also appear from the limited data available that the species richness of epigeic invertebrates collected in pit-fall traps decreases as the annual input of leaf litter (Specht and Brouwer, 1975) from the overstory decreases from the humid to the semi-arid climatic zone in the Mediterranean-type climate of southern Australia (Table 3; after Greenslade and Majer, 1985, and Specht, 1988).

Dryland Vegetation Continua

As the depth of nutrient-poor soils becomes shallower, less soil water is available for evapotranspiration, the transport of

Figure 6 The relationship between species richness of the understory in the open-forest on the serpentinite soil catena in Central Queensland (Batianoff *et al.*, 1997; Specht *et al.* 2006).

phosphate and other nutrient ions in the transpiration stream is reduced, and the growth of the overstory is limited (Figure 8(a); Specht and Specht, 2010). The low level of phosphate and nitrogen ions in the soil influences mycorrhizal association in roots of seedling eucalypts (Burrell, 1981). In extreme situations, such as on serpentine substrates, the foliage projective cover of the overstory, the annual shoot growth (per hectare), and the stand height are all reduced (Figure 8(b)). As more solar radiation penetrates the gaps between the trees, both the foliage projective cover and the species richness of the understory increases. The sum of the foliage covers of overstory and understory strata remains a constant (Figure 8(c)) in equilibrium with the evaporative aerodynamics (Figure 1) of the area (Specht and Morgan, 1981; Specht, 1983; Specht *et al.*, 1990).

Wetland Vegetation Continua

The density of the overstory, and hence its foliage projective cover, decreases as the soils become more waterlogged (anaerobic) in wetland continua (Specht, 2009). The foliage projective cover of the wetland understory increases to maintain the constant sum of the foliage projective covers of overstory and understory strata. However, unlike the increasing species richness in the vegetation continuum on dryland soils described in the previous section, species richness of the wetland understory decreases in proportion to the number of months the roots are subjected to waterlogging.

Postfire Succession

The shading effect of the overstory on the species richness in the understory has been demonstrated when long-lived shrubby species, such as *Banksia ornata* (Proteaceae),

Figure 7 (a) The number of species of small mammals recorded in ecosystems in tropical and temperate Australia plotted against the number of species of vascular plants recorded in the understory of each plant community. (b) The number of species of lizards, snakes, and frogs recorded in ecosystems in temperate Australia plotted against the number of species of vascular plants recorded in the understory of each plant community (based on Specht and Specht, 2002).

Table 3 Number of groups^a of epigaeic invertebrates collected (throughout the year) in pitfall traps established within four vegetation formations typical of humid to semiarid mediterranean-type climates of southern Australia^b

^cMonthly actual/potential evapotranspiration per millimeter of available water.

**Figure 8** The relationship between (a) stand height and nitrogen and phosphorus supply, and for serpentine substrates, (b) stand height of the overstory, and (c) foliage cover of the understory and overstory foliage cover in the open-forest on the serpentine soil catena in Central Queensland.

regenerate from seed in a secondary succession following the fire that regularly razes Australian heathlands (Figure 9). Application of phosphate fertilizer to these nutrient-poor ecosystems results in more rapid growth of overstory shrubs to the detriment of the understory species (Specht and Specht, 1989c).

Long-lived overstory species, regenerating from root-stocks after fire, rapidly develop maximum foliage projective cover in the overstory which shades out understory plants. However, the sum of the foliage projective covers of overstory and understory strata remains a constant throughout the post-fire succession (Specht, 1969).

Tall open-forests of mountain ash (*Eucalyptus regnans*) in south-eastern Australia are killed by fire. Dense stands of saplings soon regenerate and over-shadow developing understory plants. Gradually over many decades the foliage projective cover of the overstory thins to the norm for the aerodynamic climate of the region and enables the understory to develop (Ashton, 1976).

Invasive Species in the Savanna Understory

In the Mediterranean-type climate of southern Australia, the grassy understory of savanna woodlands has been invaded by short-lived herbaceous species. These introduced plants deplete soil water during their spring growing-season, before the late spring into summer growth rhythm of the native perennial grasses. Species richness of the understory is increased as the growth of the perennial grasses slowly declines (Specht, 2000). The species richness of the understory is further increased by destruction of overstory plants (Specht *et al.*, 1990).

Species Richness of Disjunct Stands of Rainforest

Foliage at the edges of isolated rainforest stands, in habitats well-watered throughout the year is abraded by aerodynamic forces, thus reducing the total amount of solar energy fixed by the stand. As the area of the rainforest stand increases, the

Figure 9 The species richness of Dark Island heathland, South Australia (Specht and Specht, 1989c) decreased as foliage cover of the overstory (*Banksia ornata*, *B. marginata*, *Allocasuarina pusilla*, and *Xanthorrhoea caespitosa*) increased with time after fire control (C) and with phosphate fertilizer (F).

number of species of vascular plants, also resident birds, increases asymptotically until it reaches a maximum when the area of the stand reaches 100–200 hectares (Specht, 1988; Specht, 2007).

Conclusions

The vegetation of Australia in the Cretaceous–Early Tertiary, fifty- to a hundred-million years ago, had developed on infertile lateritic soils, which extended across the Gondwanan super-continent of which Australia was part. The tropical and temperate rainforests, savanna and heathy floras of Australia therefore show strong family and generic (sometimes specific) affinities with the floras of India, Africa and, to a lesser extent, with South America (Specht, 1981).

Although Australia was at this time contiguous with Antarctica at latitude 60–65° S, palaeo-oxygen analyses of sea-bed sediments indicate that the climate was subtropical with a mean annual temperature of 19.5 °C (Specht *et al.*, 1992). Increasing aridity during the Tertiary (Martin, 2006), as well as the movement of the Australian Tectonic Plate northward towards the Equator at 66 mm per year (Wellman and McDougall, 1974), imposed great stresses on the Australian vegetation. Remnants of the Gondwanan flora persisted as fragments in more humid habitats. In addition, a great diversity of taxa evolved during the Early Tertiary to occupy the greater part of the continent, which today experiences varying degrees of seasonal drought (Specht, 1981; Specht and Specht, 1999). The convergence of the Australian Plate with the Sunda Plate about 15 million years ago allowed some migration of the Australian flora northward onto Sundaland, but little, if any, migration southward from southeast Asia.

The evaporative and frictional forces of the atmosphere, flowing over and through the vegetation across the Australian

continent, molded foliage distribution and structure within all plant communities; distinctive plant formations resulted from the perhumid to the arid evaporative zone, from the tropical to the temperate region. Species richness (per hectare) of vascular plants in the overstory of Australian plant communities is correlated with the annual shoot growth (per hectare) of that stratum. Similarly, the species richness of vascular plants in the understory is related to annual shoot growth in that stratum – an attribute influenced by the amount of solar radiation transmitted through the overstory stratum.

The species richness (per hectare) of nonarboreal vertebrates is correlated with species richness of the understory stratum. Species richness of epigeic invertebrates appears to depend on the annual input of leaf litter from the overstory foliage. The diversity of TWINSPLAN floristic groups and associated vertebrates is also correlated with the optimal annual shoot growth (per hectare) of the overstory stratum of Australian plant communities.

The community-physiological processes that determine the species richness of vascular plants, vertebrates, and invertebrates and the diversity of floristic groups need urgent scientific investigation before they will be better understood.

Glossary

Dipterocarp A member of the Dipterocarpaceae family (comprising 22 genera) of South Asian and African timber trees.

Mast fruiting A period or year in which a heavy crop of fruits/seeds is synchronously produced by trees and shrubs: This phenomenon, uniquely characterized by synchronicity, high variability, and periodicity of heavy fruit production, distinguishes it from nonmasting plants.

Natural regeneration The process of replacement by natural seedlings in gaps created by the selective cutting of marketable timber.

Pioneer guild The first groups of species to colonize a newly formed or denuded habitat.

Primary forest Forests that appear to be undisturbed by human influence.

Secondary forest Successional forests growing in areas where in the past the forest cover had been completely removed.

Shifting agriculture The practice of clearing a plot of land for cultivation for a short period of time, then abandoning it and allowing it to revert to its natural vegetation when the cultivation moves to another plot.

Silviculture An applied science and branch of forestry concerned with the theory and practice of controlling forest establishment, composition, and growth.

Succession Replacement of one kind of population/community by another in a habitat through a regular progression over time.

Taungya The Burmese term for an agricultural system in which crops are interplanted with plantations of trees. As the trees grow and shade the areas, cultivation of crops is abandoned.

Introduction

In the nearly 10 years since the original version of this review was written, hundreds of studies of forest management on biodiversity have been performed and many dozens have been published in peer-reviewed journals. The basic conclusions of the earlier review, presented rather tentatively at the time, have generally been strengthened by this increase in evidence; more importantly, significant new generalizations can now be made with some confidence.

Clearly, forests are being managed for a variety of goals. The precise impact of different management systems on biological diversity is still difficult to predict in particular cases, although there have been literally hundreds of studies of forest ecosystems managed for the production of timber over the last decade. Here the authors provide a perspective on changes in biodiversity in forests managed principally for timber. The concepts and principles of large-scale forest management for a more diverse range of goods and services are still under development, although traditional societies have managed forests for such purposes for centuries. Here the authors first outline various systems of management and then describe the extent of knowledge about their effects on forest biodiversity. The effects of these systems vary according to a number of factors, including the type of forest, the landscape matrix in which the forest is embedded, the nature and intensity of the management system, and the scale and method of analysis chosen by the observer. Forests are complex ecosystems with subtle and complex interrelationships, many of them unknown in detail and changing over time. The potential for variation in each of these factors is great, making generalization across specific cases tenuous.

The final section looks at efforts – increasing in number over the last 10 years – to extract general principles from the great multitude of individual studies of the effects of forest management. Individual studies have examined a vast range of forests types, harvesting and management systems, and target taxa. They have been carried out at a range of scales, from microhabitat to landscape, and have measured a broad panoply of physical parameters. Extracting the essential lessons from this mass of material is difficult but urgent, since the major barriers to more consistent and effective forest management remain political and institutional. Overcoming such barriers requires the clear and persistent communication of major trends.

Forest diversity may be examined at various levels, including ecosystem, landscape, population, and genetic levels. It is advantageous to keep these multiple levels in mind as one considers forest management systems. Since the changes effected by management on forest biodiversity do not happen all at once, but are mediated through a chain or sequence of influences both spatially and over time, this discussion is organized sequentially. The authors begin by describing the structural changes imposed on forests by management operations or activities. These structural changes determine the ensuing abiotic or environmental conditions within the forest at the small and medium (local and regional) scales. Structural changes and altered abiotic conditions combine to produce a variety of biotic changes, including changes in species composition and abundance, productivity, population density and distribution, and so forth. It is thought that these changes may also affect long-term ecological interactions and processes. Thus, the original structural alterations to forests result in changed environmental conditions, which in turn trigger

changes at the species, population, and community levels. Large reductions in effective population sizes may result in genetic alterations and impoverishment. In addition, it is important to keep in mind that virtually every managed forest experiences a variety of indirect synergistic anthropogenic effects, namely human activities not part of the management itself but facilitated by it. These may include increased incidence of wildfire, hunting, shifting agriculture, and others. Taken together, these activities may multiply the overall impact of the management system.

Management Systems

Systems of forest management vary widely throughout the world in response to ecological, social-institutional, and political factors. Use of the phrase management system need not imply that management is in each case applied in a planned, thoughtful, or consistent manner, but only that it is systematic in the sense of being a pattern of human manipulative activities governed by a specific common goal. These activities may be carefully planned and controlled interventions or they may be haphazard patterns of one-time individual extractive activities, without much overall guidance. Thus, we use the word management rather broadly.

Timber Management

Clearing Systems

At one extreme of a continuum of management systems for the extraction of timber are systems of forest clearing, with or without replanting to stimulate regeneration. Clearing systems have been used most often in temperate forests. These forests have relatively low numbers of tree species and therefore a relatively high density of commercially useful species per hectare. However, some tropical forests, such as some of the dipterocarp-dominated forests of Southeast Asia, may also have sufficiently dense stands of commercial trees to make clear-cutting an economic option. If there are residual non-commercial trees, they may be girdled or poisoned to produce even-aged stands in which commercial species predominate. There have been experiments with various geometries of clear-cuts, intended to aid in natural regeneration and the preservation of wildlife habitat. Examples are the checkerboard patterns in the Pacific Northwest of the United States and Canada and the strip shelter-belt system of Palcazu in Peru. Patterns of this type have as their goal the reduction in area of the individual gaps, and thus the reduction in distance between the edge of the remaining forest and the center of clear-cut areas. The underlying idea is to increase the likelihood of propagules from the forest finding their way into the clear-cut area and regenerating the stand. There have also been attempts to develop timber management systems that use natural gaps as models, but these are considered selective logging systems (see Selective Logging Systems).

Other forest management systems involving clearing are replacement systems, in which plantations of indigenous or exotic species are established after clearing. These have been widely used in temperate forests and less so in the tropics,

partly because they often involve a larger initial investment in silviculture. The even-aged stands which result are seen as advantageous in terms of accounting and the efficiency of silvicultural operations, but they have been vulnerable to outbreaks of pests and disease and, as highly simplified ecosystems, have been criticized as deleterious to biodiversity.

Selective Logging Systems

In many species-diverse tropical forests, clear-cutting is neither an economically nor an ecologically appropriate option, since only a few tree species are commercially accepted – although the number of accepted species is rising fast in response to a number of technical and industrial drivers. Moreover, conspecifics are widely scattered, and infrastructure including roads and rural mills may be sparse. In such managed forests, trees are selectively logged. Selective logging is a general term encompassing a wide array of management systems that vary widely with respect to spatial and temporal scale, harvesting intensity, planning, and oversight. Selectivity of species to be removed does not necessarily translate into selectivity of overall impact, so the residual forest may be affected indiscriminately even by the selective extraction of only a few trees per hectare.

Tropical forest management systems were adapted from the Central European forestry tradition, which was exported to India and Burma during the nineteenth century. Natural regeneration systems, or polycyclic systems, minimize silvicultural interventions by relying on natural regeneration after the harvest of a relatively low number of trees per hectare. These systems result in uneven-aged and multispecies stands, which are thought to provide the best opportunities for biodiversity conservation as part of the management plan. However, a variety of assumptions about regeneration patterns must be made, many of which have been questioned by foresters, and conclusive evidence of long-term sustainability is lacking.

Natural regeneration systems with adaptations to regional conditions have been developed in Malaysia (selection management system), Ghana (modified selection system), Suriname (Celos silvicultural system), Trinidad (periodic block system), and Queensland, Australia (Queensland selective logging system). Each of these has made important strides toward solving technical silvicultural problems, but in many cases sociopolitical obstacles have been more severe. Nevertheless, research is showing that where careful reduced-impact logging (RIL) is carried out, the impacts can be much smaller than in conventional logging (e.g., Smith *et al.*, 2005; Meijaard *et al.*, 2006; Lagan *et al.*, 2007; Putz *et al.*, 2008), and guidelines for tropical and temperate zone forests are being published (e.g., Thorpe and Thomas, 2007).

Salvage Logging

Salvage logging is the practice of extracting boles from burned-over or otherwise disturbed forest areas in order to minimize the loss of commercial timber. Boles tend to degrade rapidly after death due to wood-boring insects, pathogens, and fungi, so post-fire salvage logging is often performed rapidly in the months following a fire. The ecological consequences of such rapid operations have been studied only recently, in particular since a controversial study was published in *Science* in 2005. It

is now clear that salvage logging can inhibit natural regeneration, help spread invasive species, distribute sediments into streams, alter plant species composition, and damage a suite of fire-associated animal species (Kurulok and Macdonald, 2004; Lindenmayer and Noss, 2006; Herrando *et al.*, 2009). These effects may be even stronger than in conventional logging because after major disturbance, forest stands and soils are particularly vulnerable to cumulative effects. The removal of 'biological legacies' including above-ground and under-ground decomposing biomass, CWD, ash, standing snags, and other natural structures that create special microhabitats, can have very long-lasting impacts (hundreds of years).

Nontimber Forest Products (NTFPs)

Timber is not the only product to be taken out of forests and marketed, nor is it the only product for which forests are managed. NTFPs include fruits, nuts, fungi, fibers, medicinal and ornamental plants, mosses, dyes, resins, gums, fuel-wood, charcoal, leaves as fodder, poles for local construction, honey, syrup, fish, and game, as well as other animal products. In some forests, these may constitute important and large-scale commercial resources; in others, they may have great local importance but fail to appear in commercial markets. Management systems for NTFPs, too, run the gamut from traditional, socially sanctioned systems to those that are legally organized and monitored. In some cases, extraction of NTFPs may affect forest biodiversity even more than timber extraction, since NTFP extraction is often done over a long period of time – over many human generations in parts of southern Asia, Southeast Asia, and Africa – and may constitute an intensive use of some species or areas. Most of the economically significant NTFP extraction systems are today found in tropical forests and include extraction of Brazil nuts, rattans, ornamental plants, and animals, fruits, and medicinal plants. Maple syrup is an economically significant and commercially developed NTFP of temperate forests.

Shifting Agriculture and Traditional Long-Term Intensive Forest Management Practices

As primarily agricultural systems, the effects of shifting agriculture on biodiversity are treated extensively in another article. Shifting agriculture is by no means the only traditional forest management practice, however. Some traditional practices have been very intensive, especially in high population density areas of Asia, Europe, and Central America, and some have been sustained over the very long term. In Japan and Europe, coppicing and pollarding systems, in which trees are repeatedly pruned back for their leaves or poles, have been practiced for centuries. These traditional systems have preserved habitat for a diversity of plants, birds, arthropods, fungi, reptiles, and amphibians that are absent from younger successional forests in the same areas. Traditions of pasturing domestic animals in commons woods, and the retaining of hedgerows, copses, and windbreaks within intensively managed agricultural landscapes, have all contributed to the survival of woodland diversity in Europe. In the tropics, traditional systems of *taungya* and other intensive agroforestry

systems have for centuries combined high forest productivity with high species diversity. *Taungya* is a Burmese word, but similar traditions of agroforestry and the combination of tree crops with ground crops and kitchen gardens may be found in Brazil, Indonesia, Malaysia, and the Indian subcontinent. There are currently attempts to reintroduce and adapt some of these traditional techniques to modern conditions, since they are thought to hold promise both ecologically and economically.

Sacred groves found throughout the world that have been "managed" for centuries for spiritual, religious, and utilitarian reasons are beyond the scope of the present discussion.

Managed Forests as Distinct from Secondary Forests

The phrase secondary forest has been used in a variety of ways in the scientific literature of recent decades. The authors reserve the phrase secondary forest for successional forests growing in areas where the forest cover has at some time in the past been completely removed, causing a break in the continuity of the vegetative cover over time, and where this break in continuity can be detected structurally or floristically. Forest historians, geographers, and archeologists have been pushing back the date for earliest detectable human impacts on forests throughout the world, and it is becoming clear that few if any forests are primeval in the literal sense of the word. Nevertheless, the authors call forests that show no obvious structural or floristic traces of human influence undisturbed primary forests.

From the perspective of forest biodiversity, the distinction between secondary and managed primary forests is important. Secondary forests consist of earlier successional stages; they are dependent on seed dispersal from outside for their regeneration and the continued process of succession. The implications of this for biodiversity will be discussed later.

Structural Alterations

Forest structure is the three-dimensional arrangement of trees and other plants, in combination with nonliving spatial elements such as soils, slopes, and hydrology. In short, structure is the physical geography of the forest, considered at a range of spatial scales. Structure includes such characteristics as canopy and understory geometry, continuity or fragmentation of canopy cover, homogeneity or patchiness of species distribution through the landscape, soil structure, and the species composition and age structure of stands. Most of these elements may be considered at micro, local, or landscape scales. Forest structure influences forest biodiversity directly through the formation of microhabitats as well as the determination of larger-scale habitat characteristics, but the relationship between structure and species diversity is complex and not well understood.

The most immediate effects of selective timber extraction systems on forest structure, of course, are the removal of the individual target trees, together with the associated incidental damage. Incidental damage generally includes removal of

surrounding vegetation to construct access roads and skid trails, damage to vegetation during felling and skidding, compaction, and scraping of soils. Harvest of as little as 3% of the trees in an area, as is not atypical in the diverse neotropical forests, may reduce canopy cover by half through incidental damage. Canopy reduction by 75% is not uncommon in Asian dipterocarp forests, where a total of nearly half the basal area of the forest may be removed. However, damage to basal area of as little as 4 or 5% has been documented in Amazonia, when less than a single mahogany tree per hectare was removed. And noncommercial harvesting projects have obtained even better harvest-to-damage ratios in Costa Rica, Suriname, Trinidad & Tobago, Ghana, Madagascar, Queensland, Australia, and other sites.

In conventional operations, the impact on undergrowth can also be substantial. In a logged area in neotropical French Guyana, nearly half of the undergrowth was destroyed during the removal of an average of only three trees per hectare. Removal and damage of vegetation opens the canopy, creating gaps and artificial edges, and often lowers the average height of the canopy, thus altering the internal vertical habitat structure of the remaining forest and, in some cases, removing most or all individuals of the larger and older size classes.

Little precise information exists on the sorts of structural damage ensuing from NTFP extraction. It is clear that damage from intensive harvesting of leaves for fodder, poles for construction, fruits, and firewood can all be substantial.

In the temperate zone forests, the structural changes in managed forests often result from changes in species composition and age structure of overstorey trees, as the multi-species stands are replaced by even-aged populations of commercially valuable native or exotic species. Such changes set in motion a number of changes in ecosystem structure (biodiversity) and function.

Vertical Structure

The vertical stratification of forest vegetation has been the subject of some debate among plant ecologists. It is clear that many forest organisms (birds, insects, and other arthropods, certain herps) partition habitat in the vertical dimension. It is less clear what effect timber management may have on this dimension of forest structure. Selective timber extraction may simplify structure, for instance, by eliminating or preferentially damaging one or several strata. However, it has been suggested that one reason for the increase in local abundance of certain species groups in secondary forests is the greater complexity of the understory structure in younger, less well developed forests. The enhanced presence of short-lived treelets, shrubs, and herbaceous plants in disturbed forests is a matter of record (Richards, 1996).

Canopy

The forest canopy, the highest layer of the vertical structure, includes most of the interface between leaf and light. As such, it is the area of greatest energy input into the forest ecosystem. In tropical or temperate evergreen rain forest, this interface may be virtually unbroken over large areas, and there is often a very distinct division, in terms of biodiversity, between the canopy layer and the understory. In seasonal, dry, or gallery-

type forests, the canopy may be much more permeable to incoming light and correspondingly less distinct in its flora and fauna.

Gaps and Edges

The creation of forest gaps through disturbances such as selective logging both enhances and diminishes species diversity and richness in different ways. Gaps increase the local heterogeneity of habitats and create microhabitats that are rare in mature forest, but they simultaneously limit the extent of undisturbed forest, thereby reducing regional habitat heterogeneity. The question of which tendency will predominate is at the heart of discussions about management for biodiversity. The answer depends partly on the characteristics of the focal species or group, partly on the extractive methods employed, and partly on the spatial scale of analysis. Alpha diversity, which is a measurement of species diversity at the community level, does not necessarily co-vary with beta diversity, namely the overall turnover of species associations in contiguous habitat patches across a landscape. In other words, local diversity may not mirror or represent regional diversity. There have been a number of suggestions that the creation of structural gaps through management systems can or should mimic the dynamics of natural gap creation through treefall, with the idea that community dynamics would thus be minimally affected. Other authors, however, have been less sanguine about the practicality of this (for reviews see, e.g., Bengtsson *et al.*, 2000 for European forests).

Gaps and forest edges may often constitute habitats not unlike the forest canopy in respect of abiotic factors such as insolation, wind, temperature extremes, and rainfall, and may therefore exhibit an analogous flora and fauna.

Forest Fragmentation

The term fragmentation is often used to summarize the landscape-level structural changes to the forest exerted by a range of human activities. Forest fragmentation is a process that may take place over centuries, decades, or years. Often, this process starts with selective logging within a matrix of natural forest and may extend over time through the development of progressively more intensive agricultural landscapes (*agrosapes*). These *agrosapes* may eventually themselves become the matrix, finally leaving only isolated "islands" of residual forest. In developed countries, urbanization, suburbanization, "exurbanization," and the establishment of extensive transport infrastructure have all contributed to forest fragmentation, especially over the past 50 years. The process of forest fragmentation, and its effects on various aspects of biodiversity, has proven to be a rich mine for ecological study. Several studies show that fragmented forests have less biodiversity than contiguous forests and that ecological and evolutionary processes that maintain biodiversity are compromised in forest fragments.

Spatial Mosaic of Forest Types

Both short- and long-term forest management actions have been shown to make radical changes in the spatial distribution

of forest types and communities at the landscape scale. Natural forests are mosaics of species associations responsive in their distribution to aspect and degree of slope, altitude, exposure to winds and storms, fire history, and soil characteristics. A forest's spatial pattern and landscape context are thought to influence the regeneration of logged areas through seed and pollen dispersal dynamics and recruitment rates. Management can alter the natural forest mosaic by superimposing on it separate patterns reflecting land-use history, regeneration dynamics and history, or simply the pattern of access for logging (Cannon *et al.*, 1998; Foster, 1992). Altered distribution of forest types, even within a continuous forest cover, can have potentially harmful (or beneficial) effects on populations of some wildlife species.

Soil Structure and Coarse Woody Debris

Effects of management systems on soils include alteration of the microstructure of large areas of forest soil through compaction and scraping, alteration of the forest floor profile through the creation of artificial pits and mounds (or the elimination of natural ones) by bulldozers, changes to the hydrology of the affected region, and losses of organic matter and nutrients that potentially threaten fertility of the site. The latter problem is perhaps most serious in dryland areas and some areas of the humid tropics, where soil structure is often less robust, lacking the highly developed humus layer and deep mineral soil profile of many forests in temperate climates. In some tropical and temperate rain forests, heavy rainfall tends to exacerbate soil problems through increased runoff from the exposed surfaces and compacted soils of roads and trails, the associated erosion of soil surfaces, and increased clogging and silting of lakes, streams, and wetlands. Old tractor tracks and landings may remain sources of direct runoff for decades, due to their low infiltration capacities. Amounts of sediment washing into streams have regularly been shown to be higher and more variable after logging disturbances. Increases in sediment off-flow by factors of between two and 20 have been measured. These sediments often contain substantial amounts of organic material. Leaching of nutrients, as large volumes of rainwater fall directly onto exposed earth and percolate through the soil, is another problem, the severity of which depends both on the characteristics of the soil substrate and on the logging techniques employed. These soil changes may over time alter species composition and structure of forest vegetation at all levels.

The absence of downed logs and decomposing coarse woody debris (CWD) in temperate zone production forests has been blamed for reductions in soil fertility. A number of plant, animal, and fungi groups depend on complex forests floor structure for habitat and nutrient availability. Several studies have also confirmed that a variety of forest stream fauna, both temperate and tropical, need CWD lying in and across the stream channel. Clear-cuts, elimination of riparian buffer strips and channel cleaning are all highly destructive practices associated with some management approaches.

All of these problems with soils are amenable to improvement through careful logging procedures. The US state of New Hampshire, the Canadian province of British Columbia,

the Forest Guild of New Mexico and the University of Maine are just some of the groups that have published guidelines for the maintenance of CWD in forestry operations (for further references, see e.g., Evans and Kely, 2010).

Abiotic Changes

Insolation, Temperature, and Wind Patterns

Direct structural changes may cause changes in a series of abiotic factors, again on several scales. Opening of the canopy alters the insolation regime in dense-canopied forests, though it may have less effect in forests with naturally sparse canopies. Sunlight reaching the forest floor has been measured at as little as 2% in closed-canopy tropical forests; selective logging raises this percentage manifold. Greater insolation has two kinds of effects: it increases the daily energy flux, especially to the lower strata of vegetation, and it raises the average temperature of both air and soil in the forest understory. Partial or complete removal of the forest canopy also increases the movement of the air column throughout the understory in response to winds above the canopy, affecting water retention, relative humidity, and transpiration rates in the understory. These changes affect the microclimates within the forest, making it warmer and drier on average. This reduces the suitable habitat for some species of plants and animals, while increasing it for others.

Hydrology

Changes in forest floor hydrology may contribute to an increase in soil disturbances such as landslides and erosion, especially in the wet tropics, where rainfall is extreme. Such disturbances may increase the area of early successional vegetation; in areas where the organic component of the topsoil layer has been scoured away, the process of succession may be halted in its early stages for a long time. Even lesser levels of disturbance to the soil due to logging have been shown to reduce concentrations of CO₂, organic matter, and nutrients through leaching. Such changes will alter competitive balances among plant populations in favor of species adapted to disturbed habitats, and to the detriment of those specialized for the relatively consistent conditions of closed-canopy forest. Some forest ecosystems are especially sensitive to changes in hydrology. Among these are mangrove forests, which depend on the regular flushing action of the tides and may be strangled by influxes of sediment from eroding soils. Lowland swamp forests, including Brazilian *varzea*, likewise may be gradually replaced by *terra firma* forests under conditions of sedimentation. Riparian forests of various kinds are important refuges for specialized plant communities, especially in arid regions. Scrub forest and other drylands forests are vulnerable to regional changes in rainfall patterns, since their plant communities may be at the edge of their ranges or environmental tolerances. Some of the most interesting and endangered forest types, in short, may be compromised by the hydrological changes that often accompany logging and other forest use.

Biotic Changes

Up till now the authors have been describing those measurable structural, abiotic effects of logging that have been documented in forests of various types worldwide. What effects do these changes have on the biodiversity, especially the species, which make up the forest?

Plants form the first, or *autotrophic*, layer of the forest ecosystem. The autotrophs are able to build organic compounds from inorganic building blocks, using energy from the sun. The other (*heterotrophic*) organisms in a forest are directly or indirectly dependent on the transformative power of photosynthetic plants for their livelihood. Therefore the authors will consider plants first. Fungi have been implicated in crucial symbiotic relationships with many forest plants and will be considered next. The most numerous primary consumers of plants in forests are the invertebrates. Primary consumers transform and recycle the organic compounds they derive from ingesting plants. This group will be discussed third. Some vertebrates, the group the authors review fourth, are also primary consumers (*herbivores*), others are secondary or tertiary consumers (*carnivores* and *omnivores*). *Detritivores*, which make up the final stage in the recycling of organic materials, are a very important component in forest ecosystems; the authors will discuss them in the context of effects on soils.

Plants

Since plants are stationary, they are most immediately influenced by changes in their abiotic surroundings. Such changes may influence plant species composition, density, evenness, community structure and associations, and plant interactions including mutualisms and parasitisms.

Early Successional Phases

A *pioneer guild* of plants is characterized by lack of shade tolerance and therefore tends to be favored in the light-rich microhabitats created by gaps. Pioneer species tend to be widespread, with airborne pollen and small airborne seeds, fast growth rates, and tolerance of a wide variety of environmental conditions, allowing them to disperse quickly into disturbed habitats. Hence, they are characteristic of managed forests, and the pioneer guild is relatively homogeneous in species composition over large regions. This can be confusing to researchers, since localized increases of plant species diversity are common following logging. Logging expands the area of forest occupied by early successional phases, boosting representation of pioneer species in small samples. These local increases in diversity are not, however, matched on the regional level, since the local increases themselves come from the regional pool. Thus, logged forests tend to become increasingly homogeneous on a larger scale.

Exotic Invasive Species

Loss of tree cover often permits the recruitment of “naturalized exotics” (species that are not natural to the area), since the special conditions under which native species are competitively superior no longer exist. The presence of exotic

plants tends to homogenize habitats and hence biodiversity. Examples of the many widespread and aggressive exotic plant problems are *Impatiens* (an Asian ornamental) in the neotropics, and the reed *Phragmites australis* in the United States.

Fungi and Mycorrhizae

A number of studies have shown that the presence in the soil of inoculate of certain species of symbiotic fungi is necessary for the regeneration and successful growth of a number of tree species, and the same may be true for other rooted plants. Soil mycorrhizae invade growing root tips and make available to them, in the course of their own metabolic processes, nitrogen and other nutrients that are otherwise locked up in the soil. Mycorrhizal fungi require certain soil conditions to flourish. When soil environmental conditions change radically – as a result of clear-cutting, for instance – these fungi may go locally extinct. Without healthy populations of the appropriate fungal symbionts, many tree species may be unable to regenerate successfully.

Invertebrates

We still know the least about the effects of logging on the first tier of forest-inhabiting animals, the invertebrates. One of the central unknowns is the number of invertebrate species inhabiting tropical forests, which is not known even to the nearest order of magnitude. Nevertheless, data on some taxa are available, and it is possible to distinguish some trends. Canopy denizens, especially flying insects such as butterflies and moths as well as flies, wasps, and bees, may be more easily seen or trapped in lower, disturbed forest, and hence may show up more easily in surveys. Like nectar-feeding and frugivorous bird species, some invertebrates may also benefit from the increased flowering and fruiting among early successional trees and vines in logged tropical forests. And many groups are adapted to the microclimates of forest edges and gaps, and so may benefit on the population level from structural changes and forest fragmentation. Nevertheless, lepidopterans and some dipterans and bee species are clearly reduced on a regional scale in disturbed tropical forests, because there are groups with very specific adaptations to the environmental conditions of closed-canopy forest. For example, the hives of the large Asian honeybee (*Apis dorsata*) are usually found on very large old trees. Certain groups of tropical flying insects depend on vertebrate dung for part or all of their nutritional requirements. These may be strongly affected by reductions in mammal and bird populations that may accompany disturbance, although some may equally benefit from the presence of horses, cattle, or other domestic animals in the landscape. Other tropical winged insects are well adapted to the conditions of closed forest and have coevolved with particular resources that may be absent or rare in disturbed forest. Examples are euglossine bees and orchid flowers, parasitic wasps and fig fruits, or lepidopteran larvae. These groups may become rare when their hosts become rare.

In the temperate zone, lepidopterans, as well as other flying invertebrates, such as dragonflies, mayflies, and damselflies, are rarely found under closed forest canopy due to both their

temperature requirements and their dependence on bodies of water during part of their life cycle. Nevertheless, these too may be affected by uncontrolled logging activities that disturb their habitats within forests, such as bogs, swampy areas, ponds, and streams. Since boreal forests are relatively species poor, approaching the conditions of a monoculture, it is unclear to what extent cyclic events – such as insect infestations or fire – may be a part of their natural disturbance regime.

The invertebrate fauna of leaf litter and soil surface shows divergent responses to logging activities. Some groups (beetles, cockroaches, and millipedes) increase significantly in both species richness and abundance in logged tropical forests. Others (spiders, mites, scorpions, springtails, and termites) decrease. Still others, such as ants, seem to be reduced in species richness while remaining abundant in absolute numbers. Many detritivores (wood-boring beetles, certain termites, and soil mites as well as fungi) are habitat-dependent on standing or downed rotting wood. Such groups appear to have been negatively affected by long-term timber management in Europe and the American Southeast, where old-growth forest structure including snags and large rotting logs has been effectively eliminated over large areas.

The effects of forest management on another important group of invertebrates, the parasites, are little understood. It is known that parasites are some of the strongest regulators of agricultural pests, and there are data showing that tropical agriculture, chronically vulnerable to pests, may actually be more successful where patches of natural forest are left between fields. Parasites and predators on insect pests may breed in forests and disperse into nearby fields, holding down pest populations.

It has often been observed that a dramatic increase in mosquito populations is a common phenomenon in logged areas, where drainage patterns are often affected. In the tropics this may constitute an important human health concern, and malaria is increasing in some areas.

In general, the invertebrates are still the least well-known of the macroscopic fauna, yet their aggregate biomass is very large and their ecological influence is difficult to overestimate. E.O. Wilson has written about the essential role played by the “little things” in maintaining a variety of ecological functions (Wilson, 1987). The reduction or absence of groups of these forest denizens may have as yet unforeseen long-term consequences for forest ecology and ecosystem functioning.

Vertebrates

John Terborgh observed that, in addition to the critical role played by Wilson’s “little things” as the foundation of an ecological pyramid, there is an important top-down regulatory role played by the “big things,” namely vertebrates and especially the large predators (Terborgh, 1988). In sites where top predators are absent, their prey populations, most of which are herbivores, tend to proliferate. This dynamic has been documented in tropical sites such as at the Smithsonian Institution Tropical Research Institute station on Barro Colorado Island, Panama, which lacks jaguar, in temperate parks devoid of wolf and puma populations, and in expanding suburbia all across North America, where white-tail deer and Canada geese are

increasingly being viewed as pests by the human population. Many of the proliferating tropical herbivores, such as the large rodents agouti and capybara, are seed predators and may be affecting the regeneration of large-seeded tree species. In temperate parks, large deer and elk populations are browsing deciduous seedlings to the ground, effectively preventing their regeneration. The lack of top predators in managed forests may significantly alter forest structure and composition, both in the short and the long term.

Vertebrate populations in forests coming under management may be affected by losses or gains in (1) habitat area or (2) food resources. The direction of change is determined both by the particular needs of each species and by the nature of the management system. The many permutations of these variables explain why we see divergent responses to management among vertebrates.

Habitat Loss or Increase

The loss of important habitat elements tends to affect the more specialized and the less mobile species most strongly, since they may not be able to disperse to new habitats. Loss of the appropriate microclimate, sufficient kinds and amounts of cover, nesting sites, or even perch sites may force species to local extinction. We know that some vertebrates depend on habitat elements found only in old, undisturbed forests. A well-known example is the northern spotted owl in the Pacific Northwest of the United States, which nests in the large hollow trees that are usually eliminated by timber management. A range of large temperate and tropical birds, including large woodpeckers, hornbills, and quetzals, likewise nest exclusively in hollows and may use and reuse the same holes year after year. Some mammals, too, are critically dependent on old-growth habitat elements for survival. The American marten, for instance, which has very little body fat yet remains active throughout the winter in cold and snowy environments, needs resting places below the surface of the snow, often under rotting stumps or large logs. Thus, although animals like the omnivorous marten may benefit from the increased seasonal availability of berries or other resources in logged forest gaps, their territories must also include areas of older forests with woody debris.

It has been shown that a number of smaller forest birds, both temperate and tropical residents, avoid gaps in forest cover such as those created by logging. Some are reluctant to cross gaps of as little as a few tens of meters. This may result from fear of predation or from physiological adaptation to a narrow range of understory temperatures and humidity levels. Under the increasingly predominant conditions of forest fragmentation, these species may find it difficult to locate appropriate habitat, even when it is available nearby.

Terrestrial amphibians, including frogs and salamanders, may often find the relatively desiccating conditions of open-canopy disturbed forest too warm and dry. Because they “breathe” partly by the exchange of gases directly across the skin, amphibians are particularly vulnerable to alterations in their microclimates. One element in the present worldwide crisis among amphibian populations may be reductions in suitable cool, moist, and shaded old-growth habitat.

However, some vertebrate populations may do well in disturbed habitats in secondary succession. Examples of this

group that have been studied are mice in temperate forest fragments, tenrecs in Madagascar, and other rodents in tropical and temperate forests, all of which may benefit from the increase in undergrowth and herbaceous ground cover accompanying management.

Loss or Increase of Food Resources

Opening the forest canopy may often stimulate a flush of new leaves or fruits as the trees and understory respond to the more generous light allowance. Many browsing and fruit-eating vertebrates benefit from this change and may seek out areas of secondary succession such as logged areas. Populations of large folivorous mammals, including elephant, tapir, duiker, gaur, bearded pig and peccary in the tropics, or deer and elk in the temperate zone, often do well in secondary forest. In the absence of predation, including human hunting, they may themselves become agents of serious ecological change by grazing and trampling large areas of forest understory. However, many of these large browsing mammals are important game animals, especially in tropical forests where hunting is particularly difficult to control. Many have evolved shyness responses to humans, and most have greatly reduced populations in areas where hunters have access.

Birds

The effects of logging on the species richness of birds are highly variable. In logged tropical forest, certain feeding guilds experience a reduction in population ranging from 25% up to 100%. Hard-hit guilds include terrestrial foragers (insectivores and frugivores) and the small insectivorous species associated with understory habitats, particularly those of the forest interior. These decreases are likely the result of reductions in the insect resource base or microhabitat changes. These findings are not completely consistent among studies, however. Some studies, for instance, have found small increases in abundance for terrestrial, understory, and foliage-gleaning species after logging in Malaysia. Substantial local increases in abundance have also been noted for generalist feeders that can supplement nectar and fruit resources with insects. The opening of the canopy often, though not always, increases the availability of nectar and fruits in early successional patches, in turn supporting more abundant populations of generalist feeders.

Primates

Primates have particularly complex responses to logging and to the presence of humans in managed forests. In the Neotropics, generalist feeders (*Pithecia* spp., *Saguinus* spp.) have been found to do well in disturbed areas, whereas frugivores (e.g., *Chiropotes* spp., *Ateles* spp.) tend to leave logged-over areas, especially when their food trees have been extracted. However, there are exceptions, such as *Callicebus torquatus*, a generalist feeder that was found to be absent from logged forest. Old World frugivores such as *Pongo pygmaeus* and *Pan troglodytes* decline sharply in population density after logging, whereas folivores (e.g., *Colobus* spp., *Gorilla gorilla*) may seek out disturbed forest for the leaf flush.

Behavioral Changes

Behavioral changes among vertebrate populations have received little attention until recently. There are substantial difficulties inherent in studying and quantifying them. Nevertheless, they should be considered a significant group of changes because their effects may be delayed until one or several generations after the disturbance itself. Examples, which have been noted, are changes in social organization and breeding behavior among primates in Malaysia, and in nesting behavior and dispersal among birds in fragmented habitats. Among animals with complex response patterns, there are doubtless many other instances yet to be studied of behavioral changes stemming from human interventions. These may affect population dynamics years or decades after an event such as logging.

Domestic Animals and Nonforest Species

Domestic animals and introduced species have been important influences on forests throughout history. In European oak and beech forests, for instance, pigs and other grazing animals were grazed in commons forests on a seasonal basis to take advantage of fruit masting. Sheep and goats have virtually eliminated forest regeneration on the once lushly tree-clad slopes of the Mediterranean and throughout the Middle East. Today, browsing of cattle is a major influence on remaining forest fragments in many areas of the tropics.

The movement of nonforest species into logged and disturbed forests is the origin of some of the apparent increases in species diversity in logged forest plots. More species of coleoptera, for instance, have been counted in logged tropical forests than in neighboring primary forest. The species lists in logged areas, however, included the names of field species that had entered the forest after the canopy had been degraded.

Aquatic Fauna

The loss of aquatic biodiversity is understudied in the tropics. Concern regarding changes in hydrology resulting from forest disturbance overlap with local community concerns, since the need to protect sources of clean water is becoming acute in many places as human populations grow. There is more information about the effects of logging on streams and aquatic life in the temperate zone. The removal or degradation of tree cover on slopes, including the construction of logging roads, often results in topsoil loss and erosion. Soil is washed downhill and ends up in streams and rivers. Silt deposition causes declines among anadromous fishes, bottom-feeding river fishes, bivalves, and other invertebrates. Heavy silt loads can have major impacts far downstream – even in some cases degrading coastal habitats such as tropical coral reefs, mangroves, and offshore fisheries. Changes in the temperature of stream water as a result of streamside vegetation loss can also have far-reaching effects on faunal diversity.

Ecological Interactions

Structural, abiotic, and biotic changes are likely to alter a range of ecological interactions and evolutionary processes. Changes

in hydrology, soils, and soil fauna, for example, should influence nutrient dynamics, which may in turn have further impacts on biodiversity. Biotic changes alone can alter species interactions. Again little is known about the impact of extractive regimes on ecosystem function and ecological interactions. The impacts are likely to be most dramatic where extracted species constitute dominant elements of forest ecosystems as, for example, the dipterocarp tree species in Southeast Asian dipterocarp forests. Indeed, much of the recent evidence that logging may influence vital interactions and ecological processes comes from such forests.

Pollination, seed dispersal, and seed predation are basic processes that profoundly influence reproductive output and regeneration of plants. By lowering the density of harvested species, logging can decrease the resources available to pollinators, animal seed dispersers, and seed predators. The vast majority of tree species are outcrossed, and in tropical forests, where most tree species are pollinated by animals, substantial declines in the abundance of food plants can result in changes in pollinators' foraging behavior. One study in Southeast Asian dipterocarp forests confirmed that logging in forests containing *Shorea siamensis* increased the average distances among the remaining trees of that species. The large distances made it difficult for the bees that pollinate *S. siamensis* to move from tree to tree, concomitantly limiting outcrossing potential. Opening up the canopy also led to colonization of the forest floor by flowering plants that attracted bees to the understory, further depriving the canopy trees of their pollinators (Ghazoul, 2001).

Reduction in the density of reproductive individuals can also result in a substantial decline in the number of seedlings. Studies have compared seedling production in logged and unlogged dipterocarp forests of Indonesia (Curran *et al.*, 1999). Logging reduced the number of reproductive individuals per hectare to 3% of the original. Seedling production in the logged forest, following a mast fruiting year, was a mere 15% of that in the nearby unlogged forests.

The same study also documented indirect effects of logging. Dipterocarps undergo mast fruiting every few years associated with local El Niño-Southern Oscillations (ENSO). Logging around the Gunung Palung National Park, the site of the study, has fragmented the once contiguous forest. Changes in land-use have apparently affected local ENSO climate conditions. As a result, spatial synchrony in mast fruiting and the level of seed production have been reduced. One result of the natural mast fruiting pattern is that copious amounts of seed are produced simultaneously. It is assumed that this "satiates" seed predators, leaving a substantial surplus of intact seeds for regeneration. However, with the reduction in seed production, seed predators are not getting "satiated," and there is little seed surplus. Even in the national park, where there is no logging, there has been inadequate regeneration because of the decrease in seed production and the movement of seed predators into the park from surrounding areas lacking mature reproductive trees.

A more recent comparative study of dipterocarp regeneration in Borneo (Bischoff *et al.*, 2005) found that 13 years after logging, succession was not proceeding as expected – valuable light hardwood dipterocarps were being suppressed. Bischoff *et al.* suggested that this may have been the result of logging forest

stands in a late but not mature stage of succession. A mast fruiting event had occurred shortly before the logging, and had produced a large cohort of largely noncommercial dipterocarp seedlings, which then benefited from the canopy opening and prevented commercial dipterocarp regeneration. Bischoff *et al.* traced this situation back to the previous major (natural) disturbance, from which the forest was still in recovery. This event was presumed to have taken place over a hundred years before, about 1878 – a salutary reminder that forest history is a central, but often overlooked, factor that may contribute strongly to the formation of present forest conditions.

These studies from Southeast Asian dipterocarp forests illustrate several of the pathways by which logging can have far-reaching and perhaps unexpected effects on forest dynamics:

- a. Removal of mature dipterocarps and the opening of the canopy (both structural changes) produce new microclimatic conditions and an altered array of understory species (a biotic change);
- b. these changes combine to produce altered foraging patterns among bees and other pollinators, compromising their efficiency in an essential ecological interaction;
- c. meanwhile, fragmentation and degradation of the forest cover alters local climatic patterns (an abiotic change), which again affect an ecological process, the mast fruiting pattern;
- d. this alters seed predation dynamics and affects regeneration, potentially influencing forest structure and composition into the long term.

Considerably more work is needed to fully understand the consequences of the altered ecological relationships brought about by logging and other extractive activities. Studies on the effects of logging have largely been restricted to the impacts on structural and biotic components. Removal of nontimber forest products may also be expected to have an impact on a diverse range of ecological interactions and processes but has received even less systematic study.

Genetic Effects and Evolutionary Processes

Alterations in density of tree species may also have a profound effect on evolutionary processes. Most trees are strongly outcrossed; outcrossing rates are highly dependent on population density. Low population density can restrict the movement of pollen among trees and result in a high level of inbreeding. Although it has been difficult to document the deleterious consequences of a decrease in outcrossing rate, it has been confirmed in several species that inbreeding does increase with a decrease in density.

In the tropics where many tree species typically occur in low densities, reduction in density due to extraction may further decrease population sizes. Small population sizes may also contribute to inbreeding. Thus, inbreeding may be increased both by the effects of decreases in density on the mating system and by decrease in overall population size.

Extraction can also remove the better-adapted genotypes from the population, leading to *dysgenic* selection, or selection for less well-adapted genotypes. Populations subject to harvest

have lower levels of heterozygosity and lower overall levels of genetic variation. Inbreeding in logged populations resulting from a decrease in density may further decrease overall levels of heterozygosity.

Genetic and evolutionary effects can be cumulative. Fragmentation, decrease in density, and reduction in effective population size all contribute to inbreeding. In trees that are highly outcrossed, increasing levels of inbreeding may be particularly deleterious in the face of a changing environment. The genetic consequences of management interventions in forest ecosystems remain poorly explored.

Synergistic Anthropogenic Effects

Still today, only a minority of extractive forest operations is performed under a management plan, and most of these are in the developed, less biodiversity-rich countries. In the tropics, by contrast, only about 96.3 million hectares of forest was under any kind of active management plan in 2005. According to the International Tropical Timber Organization's (ITTO) comprehensive review of the status of tropical forest management (ITTO, 2006), that represents 27% of the total natural 'production forests' of the tropics (352.5 million hectares). The ITTO survey, based primarily on data submitted by the then 33 producer-member countries of the ITTO, also asserted that 25.2 million hectares of tropical 'production forest' (7% of total tropical production forest), plus 11.2 million hectares of tropical 'protection forest' (2.4% of this designation), are being managed 'sustainably'. Together with 14.3 million hectares of planted forests under certification for sustainable management, this would sum to a grand total of 858.84 million hectares of tropical 'Permanent Forest Estate', of which 36.4 million hectares were being managed sustainably in 2005. If that is true, it would represent a 25-fold increase over the less than 1 million hectares of sustainably managed tropical forests estimated by the Poore *et al.* study of 1989. Nevertheless, it would still mean that only about 4.2% of all tropical forests were being sustainably managed in 2005.

The absence of planning and long-term control most often results in a series of secondary effects, including increased hunting, fire, invasion by exotic species, mining activities, shifting agriculture, and illegal logging, which may far exceed the effects on biodiversity of the original management operations.

It has been noted that large amounts of secondary vegetation and brush tend to alter the understory structure of cut-over areas. The role of such vegetation and brush in fueling forest fires, both in temperate forests and even in the relatively fire-resistant moist tropical forests, has received increasing attention in recent years (e.g., Nepstad *et al.*, 1999; Blate, 2005; Laurance and Useche, 2009; Lindenmayer *et al.*, 2009). It is clear that large-scale fires are altering microclimatic conditions over wide areas of tropical Asia and South America. In some of the drier temperate forests, for instance parts of the US West and the pine barrens of the Atlantic seaboard, vegetation communities have evolved under the influence of regular low-intensity fires. The suppression of such fires during the past century has altered the makeup of these communities and in some cases lowered their resistance to large destructive

conflagrations. Reintroduction of controlled fire regimes is beginning to allow the native species to return and compete successfully with exotic species. A somewhat contrasting case is found in certain areas of the dry tropics, which are, as a group, some of the most highly altered and degraded forest ecosystem types. Here, degradation of the native plant assemblages and hydrology has virtually eliminated the forest's ability to regenerate itself in the face of continual incursions of fire. In such areas, putting a stop to forest fires over at least the next several decades is seen as a key step to restoring the natural plant communities.

Sharp increases in hunting after logging, too, remain the object of attention (Struhsaker, 1997; Oates, 1999; Robinson *et al.*, 1999; Laurance *et al.*, 2006; Poulsen *et al.*, 2009). Logging requires roads. Particularly in the tropics, where hunting is often unregulated, logging roads provide easy access for hunters and their vehicles into previously remote areas. Logging crews themselves are often the first hunters in a newly accessed area, both for their own consumption and for commercial markets. Others quickly follow them, and pressure on the game animal species can become intense.

In many parts of the tropics, one of the most intractable effects of logging is settlement by colonists eager for new agricultural land. Colonists follow the logging crews, entering the forest along logging roads, carving out homesteads, and planting crops. Since such movements tend to fragment and finally convert forest to agricultural land, they are clearly some of the most deleterious influences on biodiversity. Further extractive activities associated with wresting a living from the forest, such as mining, fishing, and trapping animals and birds, tend to accompany colonization and increase pressure on forest resources in a multitude of ways.

Demonstrating the multiple indirect effects that logging and its attendant activities such as road-building can have in remote tropical forests show that destructive fires too are closely associated with roads in the Brazilian Amazon. Interestingly, indigenous reserves, strictly protected reserves and restricted use reserves all had about the same effect in reducing the incidence of destructive fires, at the rather coarse scale of the satellite data used in this study.

Anthropogenic impacts compounding and altering the effects of logging are by no means limited to the tropics. The spread of invasive species like the Hemlock Woolly Adelgid in North America has interacted in some surprising ways with timber harvest, including encouraging the use of 'salvage' logging and biomass removal (e.g., Kizilinski *et al.*, 2002). The proliferation of nonnative tree species in intensively harvested southern European forests affects forest elements such as overwintering bird species, especially bark foragers (Laiolo *et al.*, 2003). Asner *et al.* (2010) produced an important attempt to integrate information about the expected impacts of climate change and land-use change, finding that combined impacts could drive significant changes in vegetation over more than 80% of Amazonian humid forests.

Essential Trends and Concluding Remarks

Clearly the extraction of forest products in managed ecosystems has an impact on biodiversity. However, natural

ecosystems are dynamic and subject to all sorts of perturbations. The critical questions in the case of managed ecosystems are the extent to which biodiversity is lost and the degree to which the losses are irreversible. A landscape perspective is important for addressing these questions, because biodiversity may increase locally while decreasing at the regional level. Moreover, some local changes may be manifestations of regional level changes, and vice versa.

In the last 10 years, there have been a number of significant attempts to synthesize what is known about the biodiversity effects of forest management. Among these is Hill and Hamer's (2004) analysis of the role of observational scale in producing results that sometimes appear contradictory – in particular as regards the conditions under which logging can appear to increase species richness. Different taxa show non-linear effects of sampling scale: the bird studies sampling at relatively *larger* scales and the Lepidopteran studies sampling at relatively *smaller* scales tended to report increased diversity following disturbance.

From this and other synthetic efforts, the following broad principles and predictions emerge:

1. Disturbances (such as logging) affect biodiversity at the scale of the *forest stand* (scale of hectares or less than one hectare) by mixing edge species and nonforest species into the pool of forest species, raising species richness at that scale. This effect is the result of the new canopy openings produced by all logging systems. Since diversity of plants, invertebrates and small mammals is often measured at that scale, these taxa often show increases in species richness in logged stands. Mobile taxa such as birds, however, tend to show reductions in species richness at this scale.
2. At the *whole-forest* scale (scale of tens of hectares, over 25 ha), many birds, less-sedentary butterflies and moths, primates and other large mammals may be censused, as well as trees. Species that prefer or depend on new-leaf flush, flowering and fruiting plants (especially pioneer species) are drawn to disturbed forest areas, sometimes producing inflated species numbers after selective logging events. Species that have specialized requirements for the habitat conditions provided by old-growth forests – including narrow temperature ranges in the understory, prevailing humidity, restricted air movement, large standing snags and CWD – tend to disappear from managed forests, so their numbers go down at the whole-forest scale unless sufficient refuges are available in the form of undisturbed areas. The presence of such refuges produces a mosaic of areas of different disturbance intensities at the whole-forest scale, raising species richness overall.
3. At the *landscape* scale (scale of tens or hundreds of ha), β diversity or species turnover typically goes down after logging, as managed forests are relatively homogeneous. All logging systems increase the size, number, and distribution of canopy gaps across a forested landscape. This inevitably affects the relative abundance of tree species, favouring pioneer and early successional species while rendering shade-tolerant late-successional species – many of which are rare in nature – prone to regional extinction. This effect may be minimized by careful selective logging systems with set-asides of sensitive areas (swamp-land, riparian areas, steep slopes, etc.) to maintain habitat heterogeneity, and limitation of secondary effects like hunting and burning. It is these uncontrolled secondary effects that are responsible for most local and regional extinctions and extirpations.
4. Future studies should account for scale effects explicitly by sampling across a wider range of spatial scales. Crucially, logging alters the relationship between α and β diversity (point diversity vs. species turn-over between sampling points). The direction and extent of the change, however, depends on the taxon being observed. This effect is difficult to quantify using available data, because taxonomic groups and sampling scale co-vary quite strongly.
5. "Conservation value" is a separate measure that must be treated as distinct from diversity, or species richness. Even in those studies that find overall increased species richness after logging, species of restricted ranges and specialized requirements often decrease or disappear, while the more generalist taxa flourish.
6. Attempts to define management procedures or outcome measurements based on indicator species, focal species or threshold levels of vegetation cover have never become widely influential. There are a number of ecological and technical reasons why such management 'short-cuts' are difficult to apply when making real-life decisions (see Lindenmayer *et al.*, 2006 for a summary). In short, ecological complexity and the complexity of environmental change mean that extracting individual phenomena as 'representatives' of broader processes is always an uncertain task.

Here we mention just a few examples of syntheses of the effects of forest management systems on particular taxa or functional groups:

- Gray *et al.* (2005) analyzed data from 57 published studies (covering 1214 species) on avian guilds and trophic organization to show how and why different groups respond differently to forest disturbance.
- Reviewing work in boreal forests, Kreuzweiser *et al.* (2008) found soils responses to logging to be highly variable and site-specific, dependent on endogenous factors including soil types, site conditions, and hydrological connectivity, as well as external factors such as the timing of harvest activities, postlogging weather patterns, atmospheric pollution inputs, and advancing climate change.
- Sodhi *et al.* (2009) analyzed the results of 120 published studies to produce a generalized statistical measure of 'ecological health' in SE Asia. The results, largely confirming intuitive understandings, are encapsulated in concluding statements such as 'SE Asia's biotas are extremely sensitive to human-induced disturbances'; 'large-scale regional deforestation may depress reproductive success'; 'deforestation and disturbance may negatively affect the demographics of SE Asian biotas' and 'the negative effects of deforestation may be partially mitigated if forests are allowed to regenerate'.
- Meijaard *et al.* (2006) observed that timber management guidelines to date mostly focus on trees and structural issues and say relatively little about managing for wild-life populations. They produce a sensible summary of

recommendations, specifically for Borneo but applicable throughout the tropics (and indeed globally), including maintaining understory vegetation and large trees for fruit, seed, dead wood, and tree hollow production, limiting canopy gaps, and reducing hunting and wildlife trade in timber concessions.

- Newton *et al.* (2009) focus on the kinds of information and analysis needed, in principle, for the further development of integrated forest modeling frameworks and participatory research approaches where there is considerable uncertainty about many parameters – as there often is still today, especially in tropical forest contexts. These approaches include Bayesian Belief Networks, spatial multi-criteria analysis, and scenario planning. Only some of these are likely to be amenable to simple, nonmathematical techniques such as could be used by nonacademic or community-level managers, especially in rural parts of developing countries. Management approaches requiring the extensive use of modeling will always limit the ability of communities to participate actively, and the ability of managers to involve and gain the trust of communities. Fortunately, it is possible to extrapolate a few relatively simple predictions about general trends, though these will always need to be adjusted to local conditions.

What is now urgently needed are sustained efforts to synthesize and communicate the knowledge encapsulated in the hundreds of publications available on the detailed effects of human commercial and management activities on forest biodiversity. Two examples of such synthetic programs are:

1. The program in Ecological Synthesis at the Fenner School of the Australian National University, led by Fischer, Lindenmayer and Cunningham (<http://fennerschool-research.anu.edu.au/cle/metaanalysis/>; see e.g., Lindenmayer & Hunter 2010), and
2. The Centre for Evidence-Based Conservation (CEBC) at Bangor University, Wales, (www.cebc.bangor.ac.uk) and its associated websites and programs: www.conservationevidence.com, run from the Department of Zoology, University of Cambridge, and the Collaboration for Environmental Evidence (www.environmentalevidence.org). CEE has set up an Environmental Evidence Library on line, containing systematic reviews of evidence on the effectiveness of human interventions in environmental management and the environmental impacts of human activities.

A landscape perspective is crucial to unraveling the confounding but synergistic effects of habitat fragmentation and climate change on biodiversity. A wide outlook is critical to understanding the impacts on the ecological and evolutionary processes and the ecosystem services that have only recently begun to be drawn into studies concerned with biodiversity in managed ecosystems. Finally, the authors do not imply that biodiversity in managed forests will always substantially decline. The low-impact harvesting regimes that are being explored all over the world may allow significant and critical goods and services to be conserved and sustainably used, particularly if such management systems are well integrated with their social and cultural milieus and are responsive to the social needs of specific regions.

Glossary

Boreal A term derived from the Greek word for north reflecting the fact that this vegetation type, the boreal forest, occurs only in the Northern Hemisphere.

Permafrost That part of the soil profile that is permanently frozen and which forms a barrier to water drainage often resulting in a wet surface condition.

Podzol A soil type highly characteristic of boreal forests and developed as a consequence of podzolization.

Podzolization The process of acid leaching whereby clay, organic particles, and mineral ions (primarily iron and

aluminum) are carried downwards and deposited in the B soil horizon, leaving an impoverished and leached A horizon. This occurs as a consequence of low temperatures and precipitation in excess of the needs of evapotranspiration.

Taiga Mostly used as a synonym for boreal forest, but more precisely it is a Russian word applied to Eurasian conifer forests described as damp and almost impenetrable. It is also described as a coniferous forest with no nonconiferous tree species except *Betula* and *Populus*.

Geography

The boreal forests are confined to the Northern Hemisphere. In North America the forest is a continuous vegetation belt stretching across the continent and spanning more than 10° latitude. Its northern limit is defined by transition to the treeless tundra; this limit extends from about 68° N in Alaska to 58° N on the west coast of Hudson Bay, and it reaches the Labrador coast at about 58° N (Larsen, 1980). In Fennoscandia it ranges from 56° N to 69° N (Esseen *et al.*, 1997), with the northern limit fringing the northern coast of Norway. Across Russia, except for a small border, the northern boundary more or less follows the Arctic coast. In parts of Siberia the boundary is up to 500 km inland (Larsen, 1980) (Figure 1). The southern limits of the boreal forest are more difficult to define because the boundaries are rarely sharp. In more oceanic areas the forest is bounded to the south by broad-leaved deciduous forest, and in continental areas transition is to parkland, dry grasslands, and semideserts. For example, in western Canada the southern transition is to subalpine forest, in central Canada it is to prairie grasslands, and in easterly regions it is to mixed deciduous forest.

Climate

There are strong relationships between the climate and the soils of the boreal regions. The characteristic nature of the climate to a large extent dictates the nature of the soils, including the permafrost, and these ultimately determine the plants and animals that live there.

General Limits

The climate of the boreal forest has been extensively documented by, for example, Hare and Ritchie (1972), Larsen

(1980), Elliott-Fisk (1988), and Bonan and Shugart (1989). The boreal forest grows where winters are too long and summers too short to support temperate forests. This typically occurs when the growing season is less than 6 months and the frost-free period less than 4 months (or fewer than 4 months with temperatures higher than 1 °C). The boundary between boreal forest and tundra corresponds approximately with (1) the line south of which the temperature is higher than 6 °C for 4.5 months (Hare and Ritchie, 1972), (2) the position of the July 13 °C isotherm with marked departures in regions with montane or oceanic influences (Larsen, 1980), or (3) where there are less than 30 days with a daily mean temperature higher than 10 °C and where the cold season lasts 8 months (Walter, 1973).

Temperature

In more general terms, Elliott-Fisk (1988) describes the climate as cool, humid microthermal, with very cold winters of 7–9 months allowing persistence of snow cover during all but the brief (3 or 4 months), relatively cool summer season. For more than 6 months of the year, the mean temperature is below 0 °C and net radiation is negative. Maximum summer temperatures generally reach the low 20s and winter minimums in the – 50s. However, yearly variation can be extreme such as in Verkhoyansk (30 °C in summer and – 70 °C in winter), but these extremes are moderated near the coast, for example, in Umeå, Sweden (Figure 2).

Precipitation

Generally, the boreal zone is characterized by having a high proportion of the annual precipitation falling as snow. Throughout most of the boreal forest annual precipitation is low, varying between 250 and 1000 mm (Figure 2). There are extremes, however, with Fort Yukon in Alaska and

Figure 1 The circumpolar range of the boreal forest. About two-thirds of the area is in Eurasia. The sector in eastern Canada lies furthest from the North Pole (Reprinted from Hare FK and Ritchie JC (1972) The boreal bioclimates. *Geographical Review* 62: 333–365.).

Verkhoyansk in Siberia each recording 180 mm annually. Some areas of western Norway with up to 2000 mm of precipitation annually have been classified as boreal rain forest. Because of low temperatures and short growing seasons, evaporation rates are low and drought is uncommon. When drought does occur, forest fires can ravage vast areas of boreal forest.

Soils

Boreal forest soils are typically low in fertility and acidic, with a thin A horizon. The most characteristic soils are podzols. However, podzols occur in a wide range of climates, not only in boreal regions, and not all boreal regions are underlain by podzols. Climate, vegetation type, chemical composition of the substrate material, and topography are the major environmental influences that produce the typical boreal podzol. The combination of low temperatures and low pH impede decomposition processes and slow the rate of soil development. The soil surface may be covered by a mat of needles up

to 3–7 kg m⁻². This mat of acidic, partly decomposed plant material is the mor litter layer. The slow but gradual decomposition of this layer continually releases a supply of organic acids that contribute to the leaching of organic particles and mineral ions (primarily iron and aluminum) from the surface soils and to the weathering of the parent material. In addition, soluble materials such as sodium, potassium, and calcium are washed out of the soil by water movement. As a consequence, the surface soils are relatively infertile and high in silica. In many cases in which the process of podzolization is prominent, the upper soil layers are gray or whitish in color. Beneath the leached layer is a zone in which materials leached downward by water accumulate, chiefly in iron-humus complexes. These deposits may be cemented into a hardpan, sometimes thick and strong enough to prevent root penetration to the lower soils. In the more extreme boreal forest climates the subsoil is permanently frozen (the permafrost). The combination of nutrients being largely tied up in the litter layer, an infertile A horizon, hardpans and permafrost results in most boreal forest trees having a shallow root network.

Figure 2 The annual variation of average temperature (●) and precipitation (■) of three locations in the boreal forest zone; Dawson in the Yukon Territories, Canada (altitude, 324 m), Umeå, Sweden (7 m), and Verkhoyansk, Russia (137 m).

Fire

Individual trees or local stands may be killed by windstorms, landslides, snow avalanches, erosion, ice storms, flooding, or insect attack, but the most important natural disturbance in the boreal forest is fire. Longer periods of unseasonably drier and warmer weather lead to a greater probability of fire, and it is the few major fires during extreme fire years that account for the majority of forests burned; this inevitably has enormous consequences for the wildlife that inhabit the forests, particularly those unable to take refuge in water bodies. In northwestern Canada and Alaska, between 60 and 80% of all fires are less than 5 ha in area, but in extreme fire years individual fires can burn up to 200,000 ha. Because fires often burn all or most of the forest floor, they influence organic matter accumulation, soil temperature, and soil moisture, and through these they impact major ecosystem processes such as nutrient cycling, energy flow, and productivity. The natural cycle of fire frequency in boreal forests of North America ranges from an average of 50–200 years to up to 500 years in wetter parts of eastern Canada. Fire frequencies in northern Sweden average from 110 to 155 years but may be as high as 270 years. Fire frequency varies considerably, both within and between regions, resulting in a mosaic landscape with different forest patches in various stages of succession. Factors contributing to the probability of a fire include tree species composition, stand structure, soil conditions, the amount and moisture content of the fuel, exposure, topography, and climate; there is much disagreement regarding whether the probability of a fire increases with stand age. Local fire chronologies indicate that fire frequency is highest in the interior, more continental areas due to a higher frequency of thunderstorms and lightning strikes; most natural fires are caused by lightning strikes. In the boreal forest of Fennoscandia there is apparently a north to south gradient with a generally lower fire frequency toward the north.

Vegetation

The boreal forest is the most continuous and extensive forest in the world. The North American and Eurasian forests are remarkably uniform in their appearance throughout their

range, both in their physiognomic structure and in species composition. Typically, there is a simple canopy layer (15–20 m high) in which numerical dominance is maintained nearly everywhere by coniferous tree species belonging to four genera: spruce (*Picea*), pine (*Pinus*), fir (*Abies*), and larch (*Larix*) (Figure 3). Species of juniper (*Juniperus*), cedar (*Thuja*), and hemlock (*Tsuga*) also occur. Next is a shrub layer (typically 1 or 2 m tall) supporting mainly broad-leaved deciduous species that are also frequently present as successional components of the forest; deciduous species rarely achieve dominance, except in some postfire successions and in the mountain birch forest in Fennoscandia. Generally, the deciduous species belong to the genera willow (*Salix*), birch (*Betula*), poplar (*Populus*), and alder (*Alnus*). The herb layer typically is poorly developed but it is enmeshed in a well-developed ground layer of mosses, liverworts, and lichens. Despite the uniformity of appearance, the tree species are unique to a particular continent, i.e., there are no circumboreal trees (Table 1). The species making up the shrub layer and ground layer may be more wide ranging, and many of the mosses and lichens are circumboreal. Bryophytes and lichens are typically a more common component of the forest floor vegetation than vascular plants. Bryophytes usually dominate on mesic and moist sites and their diversity in boreal forest is higher than in most temperate or tropical forests. Lichens also contribute significantly to diversity in boreal forests, especially on drier and northern sites, and particularly in the ground layer of pine heaths and on rocky ground.

Because there are few species of trees, the boreal forest gives an impression of monotony, but this is misleading even though they are floristically impoverished compared to most other vegetation formations of the earth. Nevertheless, these forests are a complex mosaic of different plant communities, and they caused Cumming *et al.* (1996) to title their paper “Boreal Mixedwood Forests May Have No ‘Representative’ Areas.” Some of the tree species are widely distributed (e.g., *Picea glauca* and *P. mariana*), but many other boreal species have more limited ranges, resulting in local and regional changes to forest composition. Throughout the North American boreal forest, a vegetation group dominated by *P. glauca* (sometimes codominated by *Abies balsamea*, *A. bifolia*, *Betula papyrifera*, or *Populus tremuloides*) is typically the climax

Figure 3 Limits of *Picea*, *Abies*, *Pinus*, and *Larix*, without regard to species. Limits are greatly generalized, being envelope curves around numerous disjunct areas. In particular, the central Alaskan distribution of *Larix* is probably disjunct from the Mackenzie Valley distribution (Reprinted from Hare FK and Ritchie JC (1972) The boreal bioclimates. *Geographical Review* 62: 333–365.).

community in relatively dry areas. A second group dominated by *P. mariana* occurs where soils are wetter, such as in bogs and muskegs. *Picea mariana* is not strictly characteristic of wet areas because it also flourishes after fire. In the European forests the Scots pine (*Pinus sylvestris*) is frequently dominant on drier soils and the Norway spruce (*Picea abies*) occurs on moister sites.

Although there are no abrupt transitions in the vegetation, changes in the dominant tree species, in the subdominant shrubs, and in the herbaceous layers can be detected. Various attempts have been made to survey and describe latitudinal and longitudinal gradients, based primarily on climatic

distinctions, and to describe the associated vegetation assemblages. For example, Larsen (1980) described seven regions in the boreal forest of North America, and Rowe (1972) described 35 regions. However, rather than describe each of these, we focus on some of the recent classifications.

Latitudinal Classification

Hare and Ritchie (1972) recognized three latitudinal zonal divisions of the boreal forest in North America: a southern closed forest, a central lichen woodland, and a northern forest–tundra ecotone.

Table 1 Major species of boreal forest trees by longitudinal section^a

Genus	North America, (55° W–160° W)	Northern Europe (5° E–40° E)	Western Siberia (40° E–120° E)	Eastern Siberia (120° E–170° E)
<i>Conifers</i>				
<i>Picea</i> (spruce)	<i>glauca</i> <i>mariana</i>	<i>excelsa</i> ^b	<i>obovata</i>	<i>obovata</i> <i>jezoënsis</i>
<i>Abies</i> (fir)	<i>balsamea</i>		<i>sibirica</i>	<i>nephrolepis</i>
<i>Pinus</i> (pine)	<i>banksiana</i>	<i>sylvestris</i>	<i>sibirica</i> <i>sylvestris</i>	<i>sylvestris</i> <i>pumila</i> <i>cembra</i>
<i>Larix</i> (larch)	<i>laricina</i>		<i>sibirica</i> <i>sukaczewski</i>	<i>dehurica</i>
<i>Hardwoods</i>				
<i>Populus</i> (poplar)	<i>tremuloides</i> <i>balsamifera</i>	<i>tremula</i>	<i>tremula</i>	<i>tremula</i> <i>suaveolens</i>
<i>Betula</i> (birch)	<i>papyrifera</i> <i>kenaica</i>	<i>pubescens</i> <i>verrucosa</i> ^b <i>kusmisscheffi</i>	<i>verrucosa</i> ^b <i>pubescens</i>	<i>ermani</i>
<i>Alnus</i> (alder)	<i>tenuifolia</i> <i>crispa</i> <i>rugosa</i>	<i>incana</i>	<i>fruticosa</i>	<i>fruticosa</i>
<i>Salix</i> (willow)	<i>Salix</i> species	<i>Salix</i> species	<i>Salix</i> species	<i>Salix</i> species

^aCertain species of nonboreal type range into southern parts of the forest. In North America, for example, these include the white and red pines (*Pinus strobus* and *P. resinosa*), *Thuja occidentalis*, and species from *Ulmus*, *Fraxinus*, and *Acer*. In Europe and Asia, species of *Quercus*, *Tilia*, and *Fraxinus* also have a limited boreal range. The taxonomies of *Betula*, *Alnus* and *Salix* are highly confused, and this table is hence only an approximate guide.

^b*Picea excelsa* should be *Picea abies* (Norway or European spruce) and *Betula verrucosa* should be *Betula pendula* (European birch).

Source: Reprinted from Hare FK and Ritchie JC (1972) The boreal bioclimates. *Geographical Review* 62: 333–365.

Closed Forests

The closed forest dominates vast areas of the southern boreal forest, and it occurs on a wide range of soil types and topographies. These forests have a closed crown with a moist, deeply shaded floor. The spruce–feathermoss community is characteristic of this zone, with either white or black spruce dominant. The *P. mariana*–feathermoss forests have a fairly uniform, moderately dense tree stratum, with an almost continuous ground cover of bryophytes. In contrast, the *P. glauca* forests are more irregular and open, having an understory of broad-leaved shrubs and herbs and a patchy bryophyte distribution. The most common moss in the black spruce forests is *Pleurozium schreberi*, whereas *Hylocomium splendens* is more characteristic of the white spruce and mixed woodlands.

Lichen Woodland

These forests are more open with a discontinuous shrub layer and abundant lichens. The transition from the southern closed forests to these lichen woodlands is usually smooth or mosaic-like but can sometimes be quite abrupt as in northern Manitoba and Saskatchewan. In some cases, a Western *Stereocaulon paschale*- and an Eastern *Cladonia stellaris*-dominated woodland have been identified. *Picea mariana* and *P. glauca* are the dominant trees in these forests, with *P. glauca* declining to the north. Because these forests are more open, light penetration

to ground level is much greater than in closed forests. Although these trees may be as tall (but less dense) as those in closed forests, the additional light promotes branching to ground level. The additional light often promotes a discontinuous layer of health plants such as crowberry (*Empetrum nigrum*) and bilberry (*Vaccinium myrtillus*).

Forest–Tundra Ecotone

Here, there are scattered and isolated trees, often deformed or prostrate, in a tundra landscape. Although this type of forest is located north of the limit of continuous forest, it is still considered boreal forest. The ecotone is more than 300 km wide in Quebec, up to 225 km wide in Central Canada, and it narrows at both its eastern and western ends.

A Longitudinal Classification

There is a remarkable similarity between the vegetation of the boreal forests in eastern North America and that in eastern Asia, with many identical or closely allied genera and sometimes species. These forests contain many different species, whereas those of the Euro-Siberian region contain few. Of all the tree species in the North American boreal forest, only *P. glauca* extends from the Bering Straits across Alaska and Canada to Newfoundland. *Picea mariana*, usually found only

on poor or wet soils, is found at the timberline toward the Arctic, and *Larix laricina* is found in the continental regions. Only two species, *P. sylvestris* and *P. abies*, are of any real importance in the boreal zone of Europe. Only in eastern regions of Europe is *P. abies* replaced by the closely related *Picea obovata*, whereas additional species are being added to the forest in Siberia (*Abies sibirica*, *Larix sibirica*, and *Pinus sibirica*; **Table 1**). Moving east, spruce gradually declines from the forest until it is entirely absent in eastern Siberia.

Peinado *et al.* (1998) analyzed the vegetation of the North American boreal forests. They identified three major sections (**Table 2**) and classified them as eight major groups (**Table 3**). The three sections coincide well with La Roi's (1967) classification for the same regions. Qian *et al.* (1998) examined longitudinal patterns of plant diversity in the North American boreal forests, focusing specifically on the southern closed forests. The central section has a higher species and genera diversity than the western and eastern sections (**Table 4**). White spruce forests are always more diverse than black spruce forests; this is a reflection of the diversity of herbaceous plants and bryophytes and not the diversity of woody plants (**Figure 4**). The diversity of white spruce forests is rather similar between western and eastern sections, but the diversity of black spruce forests is much higher in the west than in the east (**Table 4**). The diversity of bryophytes is remarkably consistent across the continent, but again there are more bryophytes in white spruce than in black spruce forests (**Figure 4**).

Animals

The boreal forest is home to many animals. It is the winter home of the migratory caribou and reindeer and the permanent home of many others. The wolf and lynx are the major predators of the boreal forest. Some of the best

examples of population cycles in animals are described from the boreal forest regions; for example, lynx (*Lynx canadensis*), snowshoe hares (*Lepus americanus*), arctic ground squirrels (*Spermophilus parryi*), red squirrel (*Tamiasciurus hudsonius*), and boreal red-backed vole (*Clethrionomys rutilus*) in northern Canada and microtine rodents, owls, capercaillie (*Tetrao urogallus*), black grouse (*Tetrao tetrix*), mountain hare (*Lepus timidus*), and red fox (*Vulpes vulpes*) in Eurasia. The causal relationships of these cycles have not been fully explained but many of the North American examples are synchronized with the snowshoe hare cycle, and Eurasian examples are synchronized with microtine rodent cycles.

In North America, other inhabitants of the boreal forest include moose, black bear, grizzly bear, deer, wolverine, coyote, marten, beaver, porcupine, sable, voles of the genus *Microtus*, chipmunks, shrews, and bats. Typical animals of the boreal forest vary slightly more from location to location than do the plants. The moose which browse on willow, birch, alder, and water plants, and the beaver which feeds on aspen, are widespread. Many birds also inhabit the boreal forest; for example, great horned owl, goshawk, spruce grouse, ruffed grouse, nuthatches, juncos, and warblers. Brown bears inhabit the boreal forest in Eurasia.

In the boreal zone of Eurasia, the diversity of mammalian herbivores is highest in the interior of the continent and declines to the east. Across Eurasia, species richness of mammalian herbivores is positively correlated to warm climate, the number of hardwood species, and the area of the boreal forest. Across North America, species richness of mammalian herbivores increases as the length of the growing season and the number of coniferous tree species increase (**Figure 5**). Given this information, it appears that indirect measures of primary productivity as well as the number of tree species can accurately predict species richness of mammalian herbivores. Bird diversity decreases from west to east across both the North American boreal forests and the Eurasian boreal forests. In Fennoscandia the

^aThe boreal forest can be latitudinally divided into three subzones: a wide zone of closed forest in the south, a narrow band of forest–tundra ecotone in the north, and a lichen woodland in the middle. These data cover almost the entire longitudinal range but focus on the southern closed forest (Modified and adapted from Qian H, Klinka K, and Kayahara GJ (1998) Longitudinal patterns of plant diversity in the North American boreal forest. *Plant Ecology* 138: 161–178.).

diversity of forest birds decreases northwards; in Finland, this occurs only in pine forests and not in spruce.

It seems that the boreal forests of Canada, and possibly Russia, differ from those in northern Fennoscandia in that small herbivore biomasses reach much higher levels and are dominated by species of hare rather than voles. In addition, the densities of many fewer species in the boreal forests of Canada are correlated with the dominant herbivore relative to the situation in Fennoscandia.

Tree death and decaying wood provide a variety of habitats for an enormous number of invertebrates. For example, in Sweden approximately 1000 species of beetle are dependent on dead trees. The most diverse fauna on snags is found during the first 2 years after the tree has died. Spruce logs have a more diverse invertebrate fauna than pine, but many invertebrates can inhabit both. Four typical stages in the succession of invertebrates on spruce logs in boreal forests have been described. Initial colonization is by bark beetles and

other primary cambial eaters along with their associated parasitoids, predators, and detritivores. Subsequent stages have been described in detail by Esseen *et al.* (1997).

Succession

Many studies of the boreal forest have shown a remarkably close fit between the plant community and the environment, especially with reference to moisture conditions and fertility level. This relationship is not static and communities are always in a process of change. The sequence of primary successional change is typically described as beginning in fens and then progressing as follows:

Fen → swamp → bog → muskeg

→ invading trees → forest

Fens develop under alkaline conditions on a peat substrate usually with standing water. Bogs are specialized communities of shrubs and herbs growing on a wet, acidic, peat substrate. The sequence becomes drier and more

mineral poor as muskeg develops, and this is followed by tree invasion.

The usual sequence of secondary succession is described as

Disturbance → annual plants → perennial herbs and shrubs
→ larger shrubs and trees → forests

However, these descriptive sequences mask a dynamic system under the influence of frequent disturbances, and the boreal forest is better considered as a disturbance forest. This means that the concept of the vegetation climax is probably not applicable because most of the tree species in these forests are incapable of self-perpetuation in climax state. They are instead, adapted to fire, and the boreal forest is usually maintained in a pre-climax state by frequent fires. Fire is the primary disturbance factor interrupting the successional process, and the frequency and intensity of fires will determine the nature and stage of succession. Local topographic, soil, moisture, and microclimate conditions and tree composition will determine the local fire regime, and if the local regional environment is patchy so also will be the frequency of fires. The consequence will be a vegetation mosaic, with each patch being at a different stage of succession and representing a different degree of recovery since the last fire. In this sense, the boreal forest climax is not a stand dominated by white or black spruce, but is a mosaic in which all stages of a successional or regeneration cycle are represented. It has been argued that if fires could be excluded from a lichen woodland for at least 200 years, then it is likely, that a closed-forest spruce--feathermoss would develop; however, fires usually occur more frequently and so the lichen woodland is perpetuated. In the absence of fire, however, it is also argued that the spruce--moss forests are able to maintain themselves for thousands of years (Pollock and Payette, 2010).

Nevertheless, immediately following a fire some species are characteristic pioneer species. Among herbaceous plants, *Epilobium angustifolium* and *E. latifolia* (fireweeds) are the most obvious. Density and cover of *Salix*, *Betula*, and *Alnus* are typically high in early pioneer stages and greatly decrease in

Figure 4 Triangular ordination showing sample plots in the white spruce and black spruce ecosystems of the North American boreal forest. Each point represents a single sample plot of 9 ha (300 × 300 m). Thirty-four of the plots were sampled in *Picea glauca* forest and 26 in *Picea mariana*. CNA, central North America; ENA, eastern North America; WNA, western North America (Reprinted from Qian H, Klinka K, and Kayahara GJ (1998) Longitudinal patterns of plant diversity in the North American boreal forest. *Plant Ecology* 138: 161–178.).

Figure 5 The number of mammalian herbivore species along a gradient from west to east (zones 1–9 across Europe and Asia and zones 1–12 across North America). Note the decline in species number as the continents meet at the Bering Strait (Adapted from Danell K, Lundberg P, and Niemela P (1996) Species richness in mammalian herbivores: Patterns in the boreal zone. *Ecography* 19: 404–409.).

later stages when they are intolerant of the shady conditions imposed by the establishing *Picea*, *Abies*, *Fir*, and *Populus*. Many questions remain concerning the nature of succession in the boreal forest. There are many regional differences, and local site conditions exert considerable influence of the successional process – both on its path and on its “final” form.

Conservation

In both Canada and Russia, vast areas of boreal forest are being cut annually, and the situation is worse in Fennoscandia. Although wood cutting is the biggest danger to biodiversity, there are additional threats from mining, pollution, road building, and dam construction. Clear-cutting vast areas of forest has profoundly altered the landscape structure in northern Sweden and in central Canada, resulting in habitat loss, habitat alteration, and fragmentation. Clearly, this will have mostly negative influences on both animal and plant biodiversity, even though some species will benefit in the short-term, i.e., weedy species such as *Epilobium angustifolium*, *Deschampsia flexuosa*, and *Calamagrostis purpurea* that are adapted to fire and other disturbances. Few data are available on the long-term effects of clear-cutting in the boreal forest, but studies from other forests suggest that herb communities do not recover in logging cycles of 40–150 years. Rotational cutting and clear-cutting will inevitably influence, or eliminate, natural fire regimes and will lead to changes in tree species composition and forest structure, a general reduction in stage age, and reduced input from coarse woody debris (Esseen *et al.*, 1997), all of which will have profound impacts on the natural biodiversity of the boreal forest.

Biodiversity must be preserved at all scales from the genetic variation within a population to heterogeneity occurring at the landscape level. There are two major approaches to preserving biodiversity in these areas: (1) sustainable management and (2) reserves of natural areas. The first approach is more applicable to areas that are already subject to intense management such as Fennoscandia, whereas the second approach can be applied where vast, relatively untouched areas still exist such as in parts of Canada and Russia.

Sustainable Management

To maintain biodiversity, we must also preserve or simulate the processes, mostly natural disturbances that produced the heterogeneity in the first place. Microscale heterogeneity may be enhanced by gap disturbance and by coarse woody debris. Larger scale heterogeneity may be enhanced by fire or insect outbreak. The management of forests itself may have effects on biodiversity, where species dependent on continuous forest cover (bryophytes, lichens, fungi) and carabids are negatively affected by management, but vascular plants positively affected (Paillet *et al.*, 2010). The emulation of natural disturbance in management techniques has been proposed as promising new technique for sustainable forest management, but the lack of consistent views on the meaning of the emulation of natural disturbance raises concerns about its use in policy making (Klenk *et al.*, 2008).

Reserves of Natural Areas

Reserves alone are not sufficient to conserve biodiversity in forests, but any such initiative for maintaining biodiversity in the boreal forest should include at least four components:

1. Large areas representative of southern closed-canopy forest, lichen woodland, the forest–tundra ecotone and each of the longitudinal elements within these must be protected.
2. In selecting these areas, attention must be given to the animal inhabitants, their abundance or rarity, and their migratory behavior, if any.
3. The minimum reserve size should be large enough to incorporate natural disturbance and maintain ecological processes.
4. The decision-making process should consider the “floating reserve” strategy (Cumming *et al.*, 1996) in which portions of a protected area could be periodically replaced in response to aging of components, unexpected large-scale disturbance, or refinements in conservation objectives.

Although much of the world’s boreal forest still remains intact with little impact from man, the impact from man has been immense in many areas. In the new millennium, there will continue to be an increasing demand on the world’s resources, including the boreal forests. Indeed, man’s impact has already been substantial in Fennoscandia (less than 5% of the boreal forest remains in a natural or seminatural state) and is increasing in the North American forests. It is tempting to argue that these forests are the world’s largest vegetation type, occupying vast areas (approximately 14 million km²) and account for approximately 12% of the world’s biomass, so the incursion of man is likely to have little impact. As described in this article, although the boreal forest is less diverse than most of the other world’s vegetation types, it is nevertheless a complex mosaic of patches with changing species composition both longitudinally and latitudinally, with no representative areas, and home to many species of mammals, birds, and other animals.

Glossary

Abyssal plain Large areas of flat areas referred to as abyssal plain from ~4000 to 6000 m in water depth.

Archaea Microorganisms that are similar to bacteria in size and simplicity of structure but radically different in molecular organization. They are now believed to constitute an ancient intermediate group between the bacteria and eukaryotes.

Biodiversity The variety of life in the world or in a particular habitat or ecosystem.

Biome A large naturally occurring community of flora and fauna occupying a major habitat.

Cryptic species Morphologically indistinguishable but taxonomically distinct species.

Cyanobacteria A division of microorganisms that are related to the bacteria but are capable of photosynthesis.

They are prokaryotic and represent the earliest known form of life on the earth.

Eukaryote An organism consisting of a cell or cells in which the genetic material is DNA in the form of chromosomes contained within a distinct nucleus.

Prokaryote A microscopic single-celled organism, including the bacteria and cyanobacteria, that has neither a distinct nucleus with a membrane nor other specialized organelles.

Protist A kingdom or large grouping that comprises mostly single-celled organisms such as the protozoa, simple algae and fungi, slime molds, and (formerly) the bacteria.

Taxon A taxonomic group of any rank, such as a species, family, or class.

Goals, Scope, and Strategy

In 2000, the Census of Marine Life was launched to assess and explain the diversity, distribution, and abundance of marine organisms throughout the world's oceans. It was organized around three questions: (1) What lived in the oceans? (2) What lives in the oceans? (3) What will live in the oceans? The answers required an ambitious international collaborative effort that ultimately took 10 years to complete, involved some 2700 scientists from more than 80 nations, 670 institutions, 540 expeditions, and a staggering 9000 days at sea. The first Census of Marine Life, released on 4 October 2010, reported life in the ocean was richer, more connected, and more impacted than previously thought. Its tangible achievements were many and included the creation of a baseline against which future change can be measured, establishment of the world's largest online geospatially referenced marine life database of nearly 30 million records, advancement of technology used to explore the ocean, and a foundation for how such large scientific investigations can be structured to

succeed. This cooperative \$650 million scientific endeavor also systematically defined for the first time both the known and the vast unknown, unexplored ocean (Ausubel *et al.*, 2010).

To accomplish its far-reaching agenda, the Census had to be global in nature, encompass all ocean realms from top to bottom, from the tropics to the poles, and include all ocean animals from microbes to whales. Three years of discussion and dozens of planning meetings preceded the first expedition and official launch of the Census in 2003.

The Census was divided into four component parts: a project that investigated historical fish populations, one that modeled future populations using a centralized database in which data were made accessible and permanently stored for future use based on input from 14 field projects that explored previously unexplored or little explored ocean areas. The oceans were divided into six realms (with respective subzones as necessary), with Census field projects developing efficient approaches for the exploration of each.

An International Scientific Steering Committee representing seven countries guided the science over the decade.

National and Regional Implementation Committees provided leadership in 13 regions around the world and extended access to expertise and resources and enhanced the sharing of knowledge and data (Figures 1 and 2).

The Census began with the question “What lived in the oceans?” Researchers undertook the challenge of constructing the history of marine animal populations (HMAP) since human predation became important, roughly the past 500

Figure 1 Shading shows the global span of 80-plus nations that participated in the Census of Marine Life. Two-thousand seven-hundred scientists participating came from more than 600 institutions and worked in 14 field projects spanning ocean realms from near shore to abyss and latitudes from poles to tropics. The global span of National and Regional Implementation Committees, headquarters of the field projects, and participating institutions such as museums ensured access to expertise and seas.

Figure 2 More than 80 nations participated in the global Census of Marine Life. Shown here is the number of participants by country.

years. This program component called the HMAP consisted of teams of fisheries scientists, historians, and economists, who initiated case studies in southern Africa, Australia, and about a dozen other regions. These case studies created the first reliable picture of life in the oceans before fishing, served to help distinguish the contributions of natural fluctuations in the environment from the effects of human activities, and reported that human impacts across-the board happened much earlier and were more pronounced than imagined previously.

Such a systematic collaboration between humanities and sciences bred the establishment of a new scientific discipline – marine environmental history – that will carry on the investigation of historic marine life populations well past the duration of the Census (Figure 3).

(a)

(b)

Figure 3 While recreational fishing removes much less sea life than commercial fishing, recreational fishers do sample marine life, especially large animals. In 1958, after an excursion on a Key West, Florida (USA) charter boat, a family of recreational fishers displayed their trophies, especially large groupers, subfamily Epinephelinae. In 2007, the size of the fish displayed by the same charter enterprise had plummeted, and the mix of species had changed. These images graphically illustrate many of the findings of the Census project that studied historic fish populations. Reproduced from Monroe County Library (top) and McClenachan L (2009) Documenting loss of large trophy fish from the Florida Keys with historical photographs. *Conservation Biology* 23(3): 636–643.

The largest component of the Census involved answering the question “What lives in the oceans?” Fourteen field projects investigated the major habitats and groups of species in the global ocean to assess the present marine life. Of these, 11 explored habitats, such as seamounts, vents, and coral reefs, or regions such as the Arctic and Southern Oceans, the Mid-Atlantic Ridge, or the Gulf of Maine. The remaining three projects surveyed animals from the top predators to zooplankton and microbes. Details of these interesting and varied field projects are provided in Section “Legacies” (Figure 4).

To answer the question “What will live in the oceans?” required numerical modeling and simulation. This component program was organized under the rubric of the future of marine animal populations, which focused on integrating data from many different sources and created new statistical and analytical tools to make predictions for marine populations and ecosystems in the future.

To complete the initiative and provide permanent access to data, the Census created a database, the Ocean Biogeographic Information System (OBIS), which in 2010 contained nearly 30 million records. OBIS will serve researchers, students, and policymakers with its vast library of spatially referenced marine life data for years to come as part of the Intergovernmental Oceanographic Commission (UNESCO) global data system. The data help define the unknown ocean, delineating areas that remain unexplored and where more research might be targeted (Figures 5 and 6).

The Census of Marine Life 2010 was unique in its global perspective, its breadth and resolution of taxonomic detail, and the diversity of ecosystems explored. It significantly enhanced knowledge about what is known about life in the ocean by exploring previously unexplored or little explored areas, following journeys of marine animals as they plied the open waters, and providing new windows into what was an opaque ocean. Along the way, it created analytical tools for predicting the future of ocean ecosystems, and contributed to a more accurate understanding of ocean life in the past. Each of these advances was aided by the core foundation of Census work: A commitment to collaboration and sharing of knowledge and data among scientists, to pushing the envelope either through adaptation of time-tested techniques or development of new technology, and to exploring places where “no one had gone before.” This approach advanced discovery, increased understanding, provided a baseline of ocean life against which future change can be measured, and will serve as a model for how future scientific endeavors might be structured to conduct research on a global level.

What was Learned About Diversity

To accomplish a biological census of the global ocean and compile an inventory of diversity, the Census focused on species. The Census compiled tens of millions of species-level observations obtained before and outside the Census and added millions of its own. The result of this species inventory is that the Census increased the estimate of known marine species from about 230,000 to nearly 250,000, found more than 6000 potentially new species, and completed formal descriptions of more than 1200 of them.

Figure 4 Census field projects sampled all major zones and realms of the oceans. Reproduced from Census of Marine Life Mapping and Visualization Team.

Figure 5 A global map of the nearly 30 million OBIS records of 120,000 species from more than 800 datasets shows the known and unknown ocean in half-degree squares by latitude and longitude. In blue areas, the Census aggregated data from before the Census began and from partner programs and institutions, often assembled by OBIS regional and thematic nodes. Yellow indicates regions with data both from Census partners and from the Census's own expeditions. Red indicates regions with data from Census expeditions where there were no prior data. The records attributable to and supplemented by the Census are numerous in the Southern Ocean, North Pacific, and along the Mid-Atlantic Ridge. Wide regions, such as the Eastern Pacific, remain largely unexplored. Reproduced from Ocean Biogeographic Information System.

Figure 6 OBIS exposes the still-to-be-explored ocean by depth as well as latitude and longitude. On a cross-section of the global oceans, the spectrum from red to blue extends from many to few or no records. The records are concentrated near shores and in shallow waters, while the largest habitat on Earth, the vast middle waters, is largely unexplored. Reproduced from Ocean Biogeographic Information System.

Figure 7 Species thought to be extinct have been rediscovered. For example, Census scientists found a Jurassic shrimp, *Neoglyphea neocaledonica* thought to have become extinct 50 million years ago. Photo: Richer de Forges B and La J (2007).

The Census found a shrimp species thought to be extinct, a clam deemed a living fossil, worms that live up to 600 years on the sunless bottom, cataloged the longest living mollusk (age up to 500 years), and identified more than 38,000 different kinds of bacteria in a liter of sea water. Interestingly, the Census did not have to go to distant places to discover new species. Large and conspicuous species in relatively well-known shallow waters still await discovery. Sampling in

Figure 8 Another species thought to be extinct but rediscovered: a living Caribbean fossil, *Pholadomya candida*, the only remaining species of a genus of deepwater clams that flourished worldwide for more than 100 million years and was thought during the 1800s to have vanished long ago. Photo: Juan Manuel Díaz.

relatively well-known shallow waters such as the Aleutian Islands (Alaska, USA) and the Great Barrier Reef Australia revealed many species presumed new to science, with some already formally identified as such (Figures 7–9).

The Census also found that rare species are common. During an 11-month study in 2007, for example, scientists sequenced the genes of more than 180,000 specimens from the western English Channel. One in every 25 readings yielded a new genus of bacteria (7000 genera in all), quantitatively demonstrating that less is known about the small than about the large. Many rare species in a sample contradict the notion of a few species predominating. Wherever Census researchers

Figure 9 Sampling near the shore of the Aleutian Islands (Alaska, USA) in 2008 uncovered a new species of large brown seaweed, the Golden V kelp, *Aureophycus aleuticus*, distinct enough to be assigned to a new genus. This kelp with characteristic V-shaped blades, or “leaves”, can grow as long as 3 m. Even the relatively well-known nearshore environment still harbors unknown species. Photo: Max K. Hoberg.

looked, they found many kinds of microbes in a sample represented by less than one in 10,000, including individuals that occur only once. They hypothesized that many microbes, now rare, could become dominant if environmental changes favor them. And the rare make up most of the microbial diversity in the oceans (**Figure 10**).

Via its digital database, the Census made possible the first regional and global comparisons of marine species diversity. OBIS allowed mapping of the levels of biodiversity in different regions of the oceans and for different taxa, and then analysis of what environments favor diversity. Two major patterns emerged from a global study of 13 taxa from zooplankton to mammals: Diversity in the open oceans peaked in midlatitude or in subtropical “strips” in all oceans, while coastal species were most diverse in tropical areas such as Indonesia, south-east Asia, and the Philippines. Sea surface temperature was the only environmental predictor highly related to diversity across all 13 taxa. An unprecedented review of all known marine biodiversity in 25 regions confirmed the coastal pattern.

The Census also helped to create the first comprehensive list of the known marine species, cataloged by the World Register of Marine Species, which surpassed 188,000 names in August 2010. Members of the Census team also helped to compose Web pages for more than 80,000 marine species in the online catalog, the Encyclopedia of Life.

The Census advanced genetic analysis, barcoding, and identification of marine species, compiling an impressive dataset of 35,000 marine species. The dataset allowed researchers to graph the proximity and distance of relations among distinct species, painting a new picture of the genetic structure of marine diversity, aptly named for artist Paul Klee (**Figure 11**).

Figure 10 This newly described microbe, a thermoacidophilic archaeon found in a hydrothermal vent deposit from the Eastern Lau Spreading Center in the South Pacific near Fiji, exemplifies the rare biosphere. Wherever Census researchers looked, they found many species in a sample represented by less than one in 10,000 of all individuals, including those that occurred only once. Photo: Reysenbach AL *et al.* (2006).

Figure 11 Klee diagrams, named for their analogy to the paintings of Paul Klee, display the genetic separation of species and the intensity of relations among species. Blocks of high correlation (red or yellow) on the diagonal reflect affinities within groups of species, corresponding to taxonomic divisions. Each species contributes a line, and a group of closely related species, such as fishes, becomes a group of lines that form a box. Klee diagrams illuminate broad patterns in the genetic structure of biodiversity. The color map depicts correlations for 5000 marine species from 10 phyla. Elasmobranchii, Actinopterygii, and Sarcopterygii are, respectively, cartilaginous, ray-finned, and lobe-finned taxa of fishes. The correlations coalesce into a coherent picture of categories of marine life. Photo: Dirk Steinke.

At the end of the decade, it was clear that much work remains to be done on diversity, including further refinement of the total number of marine species. Researchers agreed that at least one million species live in the world's ocean, possibly many more, and for microbes, there may be tens or even hundreds of millions of different kinds, awaiting discovery.

What was Learned About Distribution

The Census found life everywhere it looked – a virtual riot of species – and in unexpected places – everywhere from at the site of a hydrothermal vent at temperatures that would melt lead to within seafloor sediments in the deep Mediterranean where Census scientists were the first to discover anaerobic animals living without oxygen. The millions of OBIS records assembled during the Census quickly display where species have been reported, and allow for creation of species range maps. Known habitats and ranges in which species are known to exist were expanded during the decadal study and Census scientists confirmed that extreme is normal for life in the global ocean (Figure 12).

Using sound, satellites, and electronics, the Census tracked thousands of animals, mapping their migratory routes and charting hotspots and breeding places across the

interconnected ocean, creating a map of “blue highways.” In some cases, the tags measured the physical parameters of the water in which the animals traveled, providing for a richer database as well as increased understanding of parameters that influence animal movements. The Census identified migratory routes and breeding areas of many marine animals. Some of the distances traveled were quite remarkable. Atlantic bluefin tuna, *Thunnus thynnus*, for example, migrate east to west and west to east across the North Atlantic about 6000 km between Europe and North America, and Pacific bluefin tuna, *T. orientalis*, make multiple crossings of the Pacific. Equally impressive as marathon swimmers, humpback whales, *Megaptera novaeangliae*, complete annual north-south migrations of more than 8000 km. Circumnavigating the entire Pacific, a small seabird, the sooty shearwater, *Puffinus griseus*, made a 64,000-km round trip from New Zealand to Japan to Alaska to Chile and back to the Southern Ocean in 1 year. This trip, averaged about 40 km h⁻¹, and marked the longest-ever electronically recorded migration. Knowing how, when, where, and for what purposes, marine animals travel throughout the global ocean is invaluable and can be used to help preserve areas and routes for important activities such as migrating and breeding (Figures 13 and 14).

Curtains of acoustic receivers on the seabed were another means to follow marine animals. Using such an array allowed

Figure 12 Anaerobic animals living without oxygen have been imagined by science fiction writers but were not proved to exist on Earth until 2010. In the deep Mediterranean, a Census team found and added three new species to the few known species of the group called loriciferans. Unknown until the 1980s, loriciferans can live their entire lives hidden in sediment on the seafloor without oxygen. The *Nanalaricus cinzia* grows to about 0.3 mm long and 0.1 mm wide, comparable to the head of a pin. Reproduced from Danovaro R, Dell'Anno A, Pusceddu A, Gambi C, Heiner I, and Kristensen RM (2010) The first metazoa living in permanently anoxic conditions. *BMC Biology* 8: 30.

Census researchers to track 18 species of acoustically tagged fish more than 3000 km from California to Alaska, year-round. The searchable public database from this network in August 2010 contained more than 9 million detections in from more than 15,000 tagged animals. The exercise demonstrated the means for tracking even small marine animals (20 g), such as salmon, over long distances and through dissimilar waters. Among the many tracked, two juvenile Chinook salmon, *Oncorhynchus tshawytscha*, survived a 2500-km trip that took more than 3 months – from the Rocky Mountain headwaters of the Columbia River to the Pacific Ocean and north along the continental shelf of Canada's British Columbia to the coast of Alaska. The research provided insight about life cycles, movement, and behavior from the point of view of the fish and showed how the mortality of young salmon is apportioned among the habitats they encounter during their early life (Figure 15).

In addition to mapping blue highways, the Census also observed traffic patterns with hosts of animals commuting at regular hours, moving back and forth to the surface from hundreds of meters below. Using new types of echo sounders that reached the seafloor as well as sonars that looked upward in deep water, the Census observed a summer rush hour when animals rose to the surface to feed. The echo sounder moored 1000 m below the surface near the Mid-Atlantic Ridge recorded fishes and plankton rising about 400 m at about 21.00 h to the zone where sunlight and photosynthesis had

produced food during the day. At about 06.00 h, they descended to the deep water below to avoid visual predators.

A new biogeography summarizing the distribution of marine life was also charted. Census researchers compared the distributions of 65,000 species of marine animals and plants and produced the first all-taxa map of global marine species diversity. These analyses distinguished 30 biogeographic regions worldwide (Figure 16).

Census research also identified animal movements resulting from changing ocean conditions, such as melting ice and temperature changes, with attendant implications for both policymakers and those who make their livings from the sea. Deep or shallow, changes in ocean temperatures, currents, and chemistry would redistribute much marine life. Census researchers predict a decline in diversity in a tropical ocean that becomes yet warmer, and an increase of diversity at latitudes of about 50–70° in both hemispheres.

Census data also revealed the unknown, unexplored ocean. For more than 20% of the ocean's volume, the Census database has no or very few records, providing a guidepost for where further exploration is needed (Figure 17).

What was Learned About Abundance

Measuring abundance of swimming and drifting life in the three dimensions of the interconnected global ocean created particular challenges for the Census. These obstacles were overcome through review of historical archives, calculation of primary production of food, and adoption of new technology to scan vast schools of fish that allowed the Census to increase knowledge about abundance of life in the global ocean.

Historic baselines of abundance were garnered from catch records, monastery records, fish bones, and other credible materials from which a snapshot of abundance was constructed. History showed people began catching marine life long ago, and their extractions were far broader in scope than imagined. Overfishing and habitat destruction were, and continue to be, the top threats to marine life associated with human activities. Declines in numbers and sizes were also documented, with about 90% of top predators in decline from historic levels. Recovery of some species where conservation efforts were implemented was also reported (Figure 18).

Many examples abound of declining size and quantity of catches. Off the North American coast after the mid-1800s, for example, commercial fishers caught swordfish, *Xiphias gladius*, in numbers varying by a factor of 10. The fish population and effort expended in fishing raised and lowered the numbers. However, the average weight of the fish, caught by either harpoons or lines, declined steadily from as much as 270 kg in 1860 to near or less than 100 kg during the decade of the Census (Figure 19).

Extractions of target species sometimes cause fast changes, as the trawl fishery off Southeast Australia between 1914 and 1950 demonstrated. First tiger flathead (*Neoplatycephalus richardsoni*) plummeted from early, high catch-rates, and then Chinaman leatherjacket (*Nelusetta ayraudi*) and latchet (*Pterygotrigla polyommata*), species abundant in the initial years

Figure 13 Reports from birds, fish, whales, and other animals carrying small tags reveal highways and neighborhoods of the vast Pacific. Census biologgers followed bluefin tuna, *Thunnus orientalis*, commuting between Japan and California and leatherback turtles, *Dermochelys coriacea*, between Borneo and Mexico. Traveling animals connect all the oceans. Reproduced from Tagging of Pacific Predators, and McIntyre AD (ed.) (2010) *Life in the World's Oceans – Diversity, Distribution, and Abundance*. London: Wiley-Blackwell.

of the fishery, virtually disappeared from catches in later years. Similar declines were measured for the once abundant Atlantic bluefin tuna, *Thunnus thynnus*, off the coast of northern Europe. Industrialized fishing and booming catches helped strip the Atlantic bluefin population in a blink of time – 1910–1950. The species virtually disappeared from the region in the early 1960s and is still rare today.

In contrast, recoveries tend to be slow. Increases are most marked for species whose exploitation ended at least 100 years ago and species that became protected in the early to mid-twentieth century.

Beyond catch statistics, Census scientists directly observed the abundance of marine life by deploying a new sensor system that tracked vast fish populations, or shoals, as well as small schools, over tens of thousands of square kilometers along the continental shelf. It was used to identify a shoal of tens of millions of Atlantic herring – comparable in size to Manhattan Island – off the coast of New Jersey in the United States. This new advanced sonar system had a range over an expanse of ocean a million times wider than could previously be studied. New sonar images, updated every minute, so

scientists could continuously monitor the size and density of the fish in shoals and the shoal's shape as they changed from hour to hour. Beginning with a density of less than one fish per square meter, one shoal grew until it contained as many as eight fish per square meter.

The Census affirmed that by weight most marine life is microbial, up to 90%. (The equivalent weight is about 35 elephants for every living person on the planet.) Marine microbes are the tiniest cogs essential to planetary functioning and maintaining the planet's habitability. Responsible for more than 95% of respiration in the oceans, their importance is hard to overstate. By turning atmospheric carbon dioxide absorbed by the ocean back into carbon to be sunk to the depths (and doing likewise with nitrogen, sulfur, iron, manganese, and more), microbes regulate the composition of Earth's atmosphere, influence climate, recycle nutrients, create extractable resources, and decompose pollutants. Scientists are testing the sensitivity of marine microbes to such changes as the creeping acidification of the seas from rising atmospheric carbon dioxide levels, to understand which microbes thrive in different environments.

Figure 14 Conservation requires knowledge of mating areas and nurseries. Spawning Atlantic bluefin tuna (BFT), *Thunnus thynnus*, swim along the slopes in the western and eastern Gulf of Mexico. Red and blue colors on the map indicate high and low probabilities of encountering a bluefin when fishing with longlines in the Gulf of Mexico during 2002 and 2005. A long line caught no tuna at the X's on the map. The narrow band of 24–27 °C where most tuna swam prompts the speculation that a small change in temperature would change the timing and location of spawning.

Figure 15 The continental-scale acoustic curtains arrayed by the Census tracked migrations of 18 species, including juvenile Chinook salmon, *Oncorhynchus tshawytscha*, thousands of kilometers along the Pacific coast of North America and in rivers, too. The red spots on the map indicate the curtains through which animals swim, signal their passage, and give clues where and how they survive in the oceans. The orange line shows migration of the salmon the size of a banana spanning 2500 km in 3 months. The acoustic curtains also revealed an unexpected, long migration of the threatened green sturgeon, *Acipenser medirostris*, along the continental shelf from US to Canadian waters. A surprising group swam north for the winter.

Figure 16 Spanning microscopic plant-like organisms to whales, the Census produced maps of global marine species using the distributions of more than 65,000 species from the Ocean Biogeographic Information System. Thirty marine biomes summarize the distributions of many species, each biome representing a region with a distinctive fauna and flora.

Figure 17 The global marine life database built by the Census exposes gaps in our knowledge of the known and unknown. The color spectrum from red to blue ranges from many to few records. Blank areas have no records of reliably identified marine life. Explorers have yet to explore much of the high Arctic Ocean for life.

Figure 18 Dark-shaded bars indicate that the estimated declines in populations of large marine animals from their historical levels average about 90%. Some recovery (shown by light-shaded bars) has been achieved by four groups, including seals, whales, birds, and such bottom-dwelling fish species as flounder and sole. These estimates for exploited species in particular, rather than all marine animals, confirm the feared declines and offer a few hopeful instances of recovery.

Figure 19 From 1860 to the present, the average weight of swordfish, *Xiphias gladius*, caught off the North American coast by either harpoons or lines declined from as much as 270 to near or less than 100 kg. A big drop occurred from 1860 to 1930.

Analyzing indirect observations from oceangoing vessels since 1899, Census researchers also discovered that the food-producing phytoplankton near the surface has declined, globally. How this decline in phytoplankton, the basis of the food web, relates to changes in abundance and biomass at higher levels of marine life, which are all dependent on it, is a major area of ongoing research.

Figure 20 Small life can form large structures. Off Chile, filamentous bacteria of the genus *Thioploca* wove mats covering an area the size of the nation of Greece. Census scientists estimated the mats to weigh about 14 million tons, about one-seventh of the weight of the annual world harvest of commercial fisheries.

Delivery of food in a “snow” from water above controls the mass of living things on the seafloor. The Census reported the quantity of life on the seafloor peaks toward polar regions, along continental margins where cool currents well up toward the surface, and where equatorial currents diverge. On the deep-sea margins, the Census unexpectedly discovered mats of bacteria extending hundreds of kilometers (**Figure 20**).

The question of whether the total weight of life in the ocean is changing remains unanswered after 10 years of investigation.

Technological Innovation

The Census focused new “binoculars” of technology into the ocean, providing a sharper focus on the world below the waves. Novel and reconfigured tools were used to explore many previously unexplored locations and helped to provide some better definition to what lives where in the huge global ocean. These new vision-expanding tools included the genetic barcoding techniques that automate and speed identification of species helping to compensate for a shortage of marine taxonomists, tagging and tracking methodologies that provide an insiders’ view of this watery world, and acoustic innovations providing abundance assessments of marine populations heretofore not possible. While advancing technology, scientists also strove to standardize sampling protocols making it possible to make comparisons across the global ocean. These tools and strategies have provided a path forward for the next generation of ocean explorers. Some of the innovations not mentioned earlier are reviewed below (Figure 21).

DNA barcoding technology has dramatically increased the accuracy and speed of known species identification, discovery, and mapping. At the end of the decade, the Census had bar-coded 35,000 marine species, which will prove invaluable for future research, as well as practical applications. The Census also championed integrated morphological and molecular genetic approaches to the analysis of zooplankton species diversity, and especially to the analysis of cryptic (i.e.,

morphologically indistinguishable but taxonomically distinct) species. The Census also pioneered shipboard DNA identification technology. Using environmental barcoding (i.e., sequencing DNA barcodes from an unsorted bulk sample), Census scientists detected 189 species of zooplankton in a sample from the western equatorial Pacific Ocean. This approach may dramatically accelerate the rate of sample and data analysis for ocean monitoring and management. The Census also spearheaded the use of “Pyrotag sequencing,” a DNA technique used to ascertain the diversity of bacteria, archaea, and protists, while providing information about their relative abundance.

The Census demonstrated new approaches and technologies for zooplankton research using technologies that provide higher spatial resolution sampling and more accurate *in situ* depictions of animal behavior. One example, the Plankton Investigatory Collaborative Autonomous Survey System Operon (PICASSO) ROV system was deployed from ships of opportunity to study deep-sea gelatinous plankton below 1000 m. This system provided many striking images of organisms never before observed alive and allowed discovery of new zooplankton species. A second novel approach was using a 10-m Multiple Opening and Closing Net, with an Environmental Sensing System (MOCNESS) trawl equipped with fine-mesh nets to sample the deep sea (below 5000 m). This allowed high-volume sampling for rare species and capture of living specimens of zooplankton and fish species – some never before seen alive.

Other innovations involved data collection and standardization. With existing data plus its own, the Census built OBIS, the largest archive of data about marine species, which is now under the aegis of the International Oceanographic

Figure 21 Census investigators explored on and beneath polar ice. Their aircraft remotely sensed animals through properties of scattered light. Marine animals themselves carried tags that stored records of their travels and dives and communicated with satellites. Fish carried tags that revealed their migration as they passed acoustic listening lines. Sounds that echoed back to ships portrayed schools of fish assembling, swimming, and commuting up and down. Standardized frames and structures dropped near shores and on reefs provided information for comparing diversity and abundance. Manned and unmanned undersea vehicles plus divers photographed sea floors and cliffs. Deep submersibles sniffed and videotaped smoking seafloor vents. And nets and dredges still caught specimens, shallow and deep, for closest study.

Commission (IOC) and International Oceanographic Data and Information Exchange (IODE) to ensure its continuation and viability for the long term. By making OBIS publicly available and connecting it to the Encyclopedia of Life and the World Register of Marine Species, and other elements of the “e-Biosphere,” the Census created an infrastructure for future research.

To standardize the global assessment of life on coral reefs and render worldwide analysis of distributions and measurement of change, the Census innovated Autonomous Reef Monitoring Structures and standardized methods for appraising marine life near shores and in the deep sea. Collectively, Census technological innovations will make ocean exploration easier, more efficient, and possible during the decades ahead.

Legacies

At the end of its decade, the Census had increased knowledge, advanced technology, changed the way marine science is conducted, and helped advance public understanding and curiosity about what lives below the surface.

Regarding knowledge, the Census reported its findings in more than 2600 papers, many freely accessible online, a report by Trew Crist *et al.* (2009) (<http://www.coml.org/highlights-2010>), two books summarizing the scientific findings by Snelgrove (2010) (<http://www.coml.org/discoveries-census-marine-life>), and *Life in the World's Oceans: Diversity, Distribution, and Abundance* edited by Alasdair McIntyre (Blackwell

Publishing, 2010) (<http://www.coml.org/life-worlds-oceans>), a third explaining the biology: *Citizens of the Sea, Discoveries of the Census of Marine Life* by Nancy Knowlton (National Geographic, 2010) (<http://www.coml.org/citizens-sea>), and a fourth explaining the Census research objectives and preliminary findings by Trew Crist *et al.* (2009) (<http://www.coml.org/results-publications/worldoceanecensus>), and a map produced by National Geographic <http://www.coml-maps.org/oceanlifemap>, as well as other Web resources including videos (<http://www.coml.org/>). The Census built the largest repository of data about marine species by compiling observations and adding its own, and then made it a publicly accessible infrastructure for future research, which governments have committed to sustain. The Census drew baselines to help nations and the international Convention on Biological Diversity select areas and strategies for greater protection of marine life. Its baselines will help assess habitat changes such as warmer water or damage from oil spills.

One prime example of the practical application of such baselines is for the Gulf of Mexico, where 140 taxonomic experts from 80 institutions and 15 countries associated with the Census established a baseline for marine life, fortuitously before the April 2009 Deepwater Horizon oil spill. A complete inventory of marine life in the Gulf of Mexico before April 2009 is available in print and digital form (<http://www.tamupress.com/product/Gulf-of-Mexico-Origin-Waters-and-Biota,5338.aspx>), which can be used to assess the impacts of the oil spill on marine life in the Gulf as well as the recovery after cleanup (Figure 22).

Figure 22 A map of marine life establishes a baseline for evaluating the outcome of an oil spill in the Gulf of Mexico. One-hundred and forty taxonomic experts from 80 institutions and 15 countries associated with the Harte Research Institute, a Census affiliate, established the baseline of known species in the Gulf of Mexico in 2009 and made it available online shortly thereafter. The data answer graphically how many species of each taxonomic group live in different sections of the Gulf of Mexico, at what depth, and on what substrate. The new database sets a baseline of 8332 species in the north-northeast sector of the Gulf, where the Deepwater Horizon rig tragedy occurred in 2010.

Summarizing technology, the Census proved new technology, such as DNA barcoding for the identification of marine life. It arrayed microphones from California past Canada to Alaska to pioneer a global ocean tracking network for animals, invented Autonomous Reef Monitoring Structures to standardize global assessment of reef life, and developed sound systems to measure abundances over tens of thousands of square kilometers. Together, these technologies show that the IOC Global Ocean Observing System (GOOS) can observe life as well as measure physical parameters.

Regarding scientific initiatives, the Census brought scientists with different interests from different nations together under one umbrella, to use standard protocols for sampling marine life from the deep sea to the near shore, to speed the adoption of good techniques, to build capacity economically, and by so doing jump started initiatives in marine research. It strengthened partnerships of scholars in the humanities and natural and social sciences to use archival research to build the picture of life in oceans past and assess changing diversity, distribution, and abundance.

A truly unique aspect of the Census was that sharing its findings with the public was an integral part of the program. It accomplished this through regular news releases, video news releases, and even “creature features” that were posted on YouTube to inspire the public with the beauty, wonder, and magic of some of the newly discovered or rediscovered marine animals. Working with National Geographic, the Census created a new two-sided wall map of ocean life that visually depicted what was learned about diversity, distribution, and

abundance and the past, present, and future of ocean life. A partnership was established with Galatee Films to ensure the scientific accuracy of the content of its feature-length documentary *Oceans*. And, the Census served as inspiration for artists around the world, from everything from sculptors to painters to cartoonists, including being featured in the syndicated cartoon *Sherman's Lagoon* and the long-running cartoon *Mark Trail*. The release of its final results in October 2010 reached an estimated 2 billion people worldwide, who as a result of the Census knew more about life in the world's oceans than they did a decade before.

How it was Accomplished

To successfully undertake a task as massive as a global census of marine life, the oceans were divided into six realms (with respective subzones as necessary), with Census field projects developing efficient approaches for the exploration of each. Realms were intended to encompass all major ocean systems and taxa, but were also selected to take advantage of the best available technologies. The approaches adopted to study these realms and the major findings in each realm are described in [Figure 23](#).

Human Edges

The continental shelves are very gradually sloping borders between the edges of continents and ocean basins. While the

Figure 23 Six realms of the global ocean studied by Census of Marine Life scientists.

shelves comprise only 10% of ocean areas, they contain most of the known marine biodiversity and lie mainly within the exclusive economic zones of nations. For the purposes of the Census, these “Human Edges,” from the high tide line to the edge of the continental shelf, were divided into nearshore and coastal zones.

Nearshore Zone

The Census defines the nearshore as the region between the high tide line and 10 m water depth. The accessible nearshore area has been studied in minute detail in many locales around the world. The nearshore, however, stretches for more than a million kilometers around all oceans and across latitudes and climates. Testing nearshore ecological hypotheses required that researchers use similar methods in nearshore areas across all latitudes, climates, and ecosystems. This linkage was accomplished in the field project Natural Geography in Shore Areas (NaGISA – “coastal environment” in Japanese).

NaGISA initiated the first global nearshore biodiversity inventory, sampling more than 200 sites and establishing more than 40 long-term monitoring sites around the world. The project discovered new species and documented species and habitats in areas not previously found, developed sampling protocols that can be applied globally, engaging communities and increasing public awareness of the importance of nearshore biodiversity (Figure 24).

Coral reefs were another nearshore system investigated. The global Census of Coral Reefs (CReefs) field project was national (Australia, USA), regional (Caribbean), and international in scope. CReefs conducted the largest concerted exploration of life in the world’s coral reefs, discovered thousands of new species and records, filled data gaps for lesser-known species, and collected thousands of DNA samples, many new, for the Barcode of Life. It also developed a standardized tool, Autonomous Reef Monitoring Structures, to assess spatial patterns of cryptic biodiversity globally and monitor biodiversity impacts of climate change and ocean acidification. Its Coral Reef Biodiversity Resource Locator aids scientists and managers globally (Figure 25).

Figure 24 Census scientists studying the near shore developed standardized protocols to establish baseline information and long-term monitoring of nearshore sites and allowed global comparison of biodiversity along the coastline.

Coastal Zone

Recent crises in fisheries have forced a re-examination of how single species are managed and new strategies for management have evolved, including for trans-boundary species in coastal nations. The Census program for assessing and explaining diversity, distribution, and abundance – especially of non commercial species – may help speed evolution of new management strategies. It accelerated and increased knowledge for the management of commercial species, while adding to general knowledge about and understanding of the global fisheries.

One coastal field project, the Gulf of Maine Area Program (GoMA) was designed to identify and collect the biological knowledge necessary for ecosystem-based management in a large marine environment. GoMA mined many data sources to assemble a list of >4000 named species in a new register and other databases, and estimated the abundance and diversity of microbes. Novel statistical analyses show that habitat explains about a third of the variation in distribution and abundance of the abundant fish and invertebrates, which can contribute to future management decisions. New technologies increase researchers’ ability to sample and record patterns of species distributions, including synoptic views of very large schools of fish (Figure 26).

Another coastal project was the Pacific Ocean Shelf Tracking Project (POST). The POST deployed the first continental-scale array to acoustically track marine animals, and followed juvenile salmon thousands of kilometers from river to ocean, estimated survival of some ocean-migrating salmon stocks, and discovered surprisingly vast migrations of sturgeon and other species across national boundaries. With an expanding library of 16,000 tracks from 18 different species from salmon to jumbo squid, the project built a clearinghouse for sharing telemetry data, contributed to the designation of critical habitat for threatened green sturgeon, and served as a prototype for the IOC GOOS Ocean Tracking Network (Figure 27).

Figure 25 At the end of the decade, the Census had installed more than 600 Autonomous Reef Monitoring Structures (ARMS), to assess spatial patterns of cryptic biodiversity globally and monitor biodiversity impacts of climate change and ocean acidification. The ARMS is the box-like structure in the foreground of the image.

Hidden Boundaries

The Census also investigated regions for which there was little prior biological data. The slope region of continental margins that begins at the edge of the continental shelf and extends to ocean basins were considered in the Hidden Boundaries category because they were difficult to sample and little studied. The deep sea floor below the base of the continental slope covers 54% of the Earth's surface, more than the total continental mass (29%). This region, from ~4000 to 6000 m in water depth, has large areas of flat areas referred to as

Figure 26 The 4000 plus species in the Gulf of Maine searchable register include the pictured sea star, *Solaster endeca*, found along the shore of Cobscook Bay, Maine. The Census project found twice as many species and thus greater biodiversity in the Gulf than previously estimated.

abyssal plain, where only very small areas have been sampled and very little was known about life. Hence, they were also included in the Hidden Boundaries realm.

Slope Zone

Exploration of continental slopes has been inhibited by distance from shore, depth, complex current systems, and geomorphology. Sonar and seismic images of the lower margins have recently revealed that apparently uniform slopes hide mixtures of rock, sand, mud, and methane hydrates. The Census project, Continental Margin Ecosystems on a Worldwide Scale (COMARGE), explored slopes of all continents during more than 60 expeditions. A meager rain of detritus was found to sustain ribbons of life along mud bottoms with highest diversity discovered at mid-slope depths. Off Mauritania, deep-sea coral structures greater than 400 km long were discovered. Elsewhere vast mats of microbe-based ecosystems lived off seafloor methane. The project documented the sensitivity of continental slopes to global changes and to exploitation of deposits of petroleum and gas (Figure 28).

Abyssal Plain

Exploration of the ocean's abyssal plains has been hindered by time, distance, and the resources required to investigate this hidden realm. The Census of Diversity of Abyssal Marine Life (CeDAMar) was launched to study the abyssal plain biodiversity of the endo-, epi-, and hyper-benthic organisms (those living in, on, or directly above the sediment).

CeDAMar explored the abyssal plains of major ocean basins, particularly the southern Atlantic and the Southern Ocean, described more than 500 new abyssal species from unicellular animals to large squid, investigated the feeding of abyssal organisms, and mapped the distribution of deep-sea life. The project compiled data for establishing protected sea-floor outside national jurisdiction and documented that climate change, human debris, and seabed mining affect abyssal life (Figure 29).

Figure 27 With acoustic tags implanted in five species of young Pacific salmon and detected by curtains of receivers along the coast, scientists reconstructed the direction, speed, and timing of migrating individuals. Signals from fish like those in the photograph showed the coastal regions and seasons that either favor or discourage survival.

Figure 28 A close-up photograph of the sea cucumber *Eynpniastes* caught at 2750 m on the continental margin in the Celebes Sea between Indonesia and the Philippines reveals its mud-filled intestine through its transparent body.

Figure 29 The tiny copepod *Ceratonotus steiningeri*, about three or four times as long as a hair is wide, was found in the Angola Basin.

Central Waters

Between the continental margins are the ocean basins and open deep water. This region was characterized by the Census

as Central Waters. These large open ocean areas are home to at least 40% of the world's primary production of biomass. The Census divided the Central Waters into the Light Zone, from the ocean surface to 200 m water depth, and the Dark Zone, from 200 m to the ocean floor.

The focus of study on the organisms that drift in the Light Zone was the question of whether this community was consistent globally. This question required molecular tools and global assessment of populations throughout the ocean. In contrast, there was no question about the basin-wide or even global connections among the large swimming pelagic animals in the Light Zone. New technologies used by the Census made it possible to provide realistic estimates of the global distribution and abundance of animals in this realm. Although many of the tracked species also spend time in the Dark Zone, they were categorized in the Light Zone realm where they typically feed.

Light Zone (Drifters and Swimmers)

The foundation of life in the oceans is the photosynthetic activity of phytoplankton, including cyanobacteria, and microscopic algae. This requires sufficient light intensity, present to ~200 m water depth depending on water conditions. In this top 200 m live the phytoplankton that comprise almost 95% of total marine productivity. The open ocean phytoplankton are consumed by a community of extremely diverse zooplankton dominated by planktonic crustaceans called copepods.

The Census of Marine Zooplankton (CMarZ) was undertaken to accomplish global-scale analysis of all marine zooplankton groups using new and emerging technologies including molecular, optical, and acoustical imaging, and remote detection. Efforts were initially focused on DNA barcoding of existing specimen collections to identify cryptic species among cosmopolitan groups. In the end, the Census of Marine Zooplankton project produced a global view of diversity and distribution of holo-zooplankton, the animals that drift in ocean currents throughout their lifespan. Researchers collected more than 10,000 samples from every ocean basin. Training 250 new taxonomists, they discovered more than 85 new species, seven new genera, and two new families, many of which are already formally described. They used genetic profiles to develop characteristic fingerprints for all the zooplankton life in any volume of water (Figure 30).

At the other end of the spectrum was the Tagging of Pacific Predators (TOPP), which worked with marine animals to create a view of vast open ocean habitats as seen by the animals themselves, especially top predators. Knowing the behavior of the top predators allows inferences about the distribution and abundance of many other organisms that live in the ocean, such as where prey species accumulate. TOPP used electronic tags to follow 4300 marine predators, representing 23 species, on their journeys throughout the Pacific Ocean. These animals undertook basin-scale migrations, moving from the poles to the tropics and from continent to continent, and followed migratory corridors to ocean "hotspots," where large numbers of individuals – and multiple species – congregate for extended periods. Tags on these "animal oceanographers" collect

Figure 30 When US and Filipino zooplankton scientists searched the Celebes Sea for new species in its deep water, they discovered and temporarily named this worm, about 10 cm long with tentacles, squidworm. One of the small animals that floats or swims weakly, the squidworm turned out to be a new species of polychaete in the class of annelid worms.

invaluable environmental data, yielding new insights into their requirements from the structure of the ocean itself (Figure 31).

Dark Zone (Mid-Water and Bottom-Water)

The challenge of investigating the Dark Zone was taken on by a multinational group of researchers who formed the Patterns and Processes of the Ecosystems of the Northern Mid-Atlantic Project (MAR-ECO). The objective of MAR-ECO was to explore and understand the distribution, abundance, and trophic relationships of the organisms inhabiting the middle and deep waters of the mid-oceanic North Atlantic, and identify and model ecological processes that cause variability in these patterns. A multidisciplinary trans-Atlantic team of researchers, led by a steering group with representatives from the United States, Germany, the United Kingdom, Iceland, Portugal, France, and Norway, carried out investigations between Iceland and the Azores using ships and submersibles. MAR-ECO explored marine life along the Mid-Atlantic Ridge, the world's longest mountain range, which rises from the seafloor 4500 m deep. Explorers found approximately 1000 species, from small crustaceans to whales, including at least 30 new species. They found both mid-water animals from deep basins and bottom-living animals along slopes. Abundance generally peaked where cool and warm waters met. Project findings supported protection of areas of the Mid-Atlantic Ridge against harmful bottom fishing totaling 330,000 km², larger than Italy (Figure 32).

Active Geology

Seamounts, hydrothermal vents, and cold seeps are geologically active areas, grouped together in the Active Geology realm. The Census project, the Biogeography of Deep-Water

Figure 31 Biologging, the use of miniaturized electronic tags to track animals in the wild, revealed unknown behaviors, movements, physiology, and environmental preferences of a variety of ocean animals. Biologging has shown that communities of southern elephant seals, *Mirounga leonina*, from different islands surround the harsh environment of Antarctica, demonstrating the principle that animals inhabit even the farthest reaches of the ocean.

Chemosynthetic Ecosystems (ChEss), was launched to discover new hydrothermal vents and cold seeps, to assess the diversity, distribution, and abundance of their fauna in relation to other chemosynthetic ecosystems, and to explain the differences and similarities at the global scale. The ChEss

Figure 32 This remarkable red worm, between 20 and 30 cm long, discovered by scientists investigating the Mid-Atlantic Ridge turns out to belong to a completely new family. In fact, it is not a worm, as they initially thought, but an “enteropneust” that has more in common with vertebrates than with worms.

Figure 33 In the inhospitable environment on a vent in the southeast Pacific near Easter Island, Census explorers discovered the yeti crab, *Kiwa hirsuta*. Given a species name for its hirsute appearance, its white, hairy look has prompted the nickname yeti for the abominable snowman, or yeti. The remarkable crab belongs to a new species and new genus and family, too.

scientific steering group identified a number of specific locations and three major priority regions – the Equatorial Atlantic Belt, the Southeast Pacific, and New Zealand regions along with the development of a database on deep water chemosynthetic species. ChEss also worked to establish close collaboration with other ocean science programs that will venture to sites of vents, helping to make future research and exploration affordable.

ChEss explored life at seeps, vents, and whale falls, where abundant life thrives, fueled by chemical reactions rather than sunlight. Using advanced robots, the project extended the known limits to such life – farther north (72°N) and farther south (60°S), deeper than 4900 m and hotter than 407 °C.

Figure 34 The variety that seamounts contribute to ocean topography can also contribute to its biodiversity. In the photograph, a bright orange brisingid sea star is prominent among corals on a seamount. The sea star is feeding by raising its arms to capture passing food from the Antarctic Circumpolar Current.

Project scientists described about 200 new species, bringing to more than 1000 the number of described species known to live without the sun’s energy (Figure 33).

The project focusing on seamounts, Census of Seamounts (CenSeam) synthesized what was known about biodiversity, which will help direct future field efforts toward a comparative ecology of seamounts. CenSeam encompassed up to 100,000 seamounts rising 1000 m or more from the seafloor. The project discovered new seamounts, species, and communities and found that seamount inhabitants broadly resemble those on adjacent continental slopes. Yet, owing to isolation and slow growth of deep animals, life on seamounts can struggle to recover from disturbances such as fishing. The project’s central repository of global seamount data is informing international negotiations about protecting areas in the high seas (Figure 34).

Ice Oceans – Arctic and Antarctic

Two Census field projects were designed to study the ocean areas at opposite poles of the Earth. They shared the need for specially equipped ice-breaking ships, forcing highly integrated sampling schedules for the entire water column from surface ice to abyssal plains. The first Ice Ocean field project launched was Arctic Ocean Diversity (ArcOD). Its goal was to assemble existing knowledge of biodiversity in the least known ocean, direct new international explorations using new technologies, and create a framework for understanding and predicting biological changes in this rapidly melting ocean.

ArcOD established the baseline of marine life in the region. Its search on, in, and under sea ice, in deep basins, and along continental shelves cataloged more than 7000 animal species, of which at least 70 are new, plus thousands of microbes. Project researchers documented recent northward extensions of ranges of invertebrate and fish species, and a rising ratio of warm- to cold-water species. Making more than 250,000 records accessible online, the project allows measuring changes

Figure 35 Deep in the frigid Canada Basin, a remotely operated vehicle of the Arctic Ocean project captured the pictured jellyfish of the genus *Crossota*.

Figure 36 The acantharians are one of the four types of large amoebae (microbial eukaryotes) known to occur in marine open waters. The 2-mm-wide specimen, about the size of a flea, was captured off Bermuda.

in Arctic life caused by humanity and natural forces (Figure 35).

Like its northern counterpart, the Census of Antarctic Marine Life (CAML) assembled rich biological data on the Southern Ocean, and encouraged biodiversity sampling on all cruises in the region, particularly during the focal period of the International Polar Year, IPY, (March 2007–March 2009). The goal was to couple this new understanding of biology with the complex current dynamics that control gene flow through the world's oceans. CAML's scientific steering group represented seven nations with research interests in the region, and extended to other South American countries participating in IPY projects in benthic biology.

CAML coordinated 18 research voyages during IPY, the widest-ever survey of the region to date, and provided the baseline for marine life in the Southern Ocean. CAML also helped establish the monitoring of its change by playing a key

role in the development of the Southern Ocean Observing System. The project documented more than 16,500 taxa, including hundreds of new species. The researchers identified a single region of seafloor life under the fastest current on the planet, found colonists from deeper water beneath melting ice shelves, and showed how Antarctic waters may incubate new species.

Microbes – The Microscopic Ocean

The number of microbes in marine environments is staggering – with estimates of tens or even hundreds of millions of them – and they have a dominant role in ocean processes. To complete the Census of Marine Life, the International Census of Marine Microbes (ICOMM) was established to develop a highly resolved biodiversity database for marine microbes and to understand how microbial populations – the oldest life on the planet – evolve, interact, and redistribute on a global scale.

Microbiologists from 25 countries joined forces and determined the range of genetic diversity, distribution, and abundance of oceanic microbes. Investigators found diversity at least 10–100 times the previous estimate. A liter of sea water contained about 38,000 kinds of bacteria. In more than 1200 widely distributed marine samples from water, sediment, and around animals, researchers found some microbes live everywhere, while others live in only a few places. They discovered a rare biosphere in which “rare microbes” account for most ocean diversity (Figure 36).

Glossary

Biogeography The study of the distribution of plant and animal life in the earth's environment and of the biological and historical factors that produced this distribution.

Geomorphology The study of the surface configuration of the earth, especially the nature and evolution of current land forms, their relationships to underlying structures, and the history of geological activity as represented by such surface features.

Land-use change The changes in the way land is used at a given location, for example, when a forested land is

converted to agricultural fields or when a forestry plantation is changed to other types of use.

Páramo This term refers to a cold and humid landscape located above the tree line.

Plate tectonics A modern geological theory of tectonic activity according to which the earth's crust is divided into a small number of large, rigid plates whose independent movements relative to one another cause deformation, volcanism, and seismic activity along their margins.

Central America as a Biogeographic Region

The definition of Central America varies considerably among sources. The most popular notion of what constitutes Central America is based on a geopolitical criterion. According to this, Central America is that region of the Western Hemisphere that constitutes the isthmus lying between Mexico and South America, encompassing the countries of Guatemala, Belize, Honduras, El Salvador, Costa Rica, and Panama. Some geographers also include at least one (Jamaica) or most (Cuba, Haiti, the Dominican Republic, and Barbados) of the Antillean Islands as part of Central America, but the most accepted views only consider the continental part of the region as Central America. However, even this widely accepted geopolitical definition is not entirely satisfactory for the purposes of this encyclopedia. A description of the ecosystems of Central America requires a more natural definition. Thus, this article will consider a biogeographical and geomorphological approach, according to which Central America is more naturally defined as an elongated, tapering isthmus that begins in the narrowest part of southern Mexico, at the Isthmus of Tehuantepec (**Figure 1**). This narrow region divides the area of volcanic rocks to the northwest from the folded and considerably faulted structures of the more conventional Central America to the east. However, a more complicated delimitation is that of the Mexican sector that extends into the Yucatan Peninsula. Although this sector naturally extends northward from Chiapas, into the States of Campeche, Quintana Roo, and Yucatan, with the vegetation following a gradient of precipitation, it reaches a very high latitude, more northerly than what typically would be considered Central America. For that reason, we have included a portion of the Peninsula, somewhat arbitrarily cut at the latitude of 20° N, leaving out the drier part of the peninsula. The southernmost limit of Central America is the valley of the Atrato River in Colombia, located just to the east of the Panama-Colombia border, where the massive Darién jungles begin.

An important biogeographic aspect derived from the location of the region is that this narrow strip of land currently connects the neotropics of South America and the Nearctic zone of North America, two major biogeographic realms of Earth. An important additional implication is that Central America currently operates as a corridor for terrestrial organisms from both realms and as a barrier to marine organisms from the Caribbean and the Pacific seas. However, such situation has not always been the case. A variety of hypotheses have been suggested regarding the possible configuration of the area in the past. That said, a consensus exists that from the latter Mesozoic, until approximately 5 or 6 million years ago in the Pliocene, no continuous terrestrial connection existed between South and North America *via* Central America. Moreover, throughout the largest part of the Cenozoic era (65 to approximately 5 Ma), the region comprised from Nicaragua to the northernmost part of Colombia was probably an archipelago similar to the Lesser Antilles of today, providing only, perhaps, an occasional pass for terrestrial life forms. Most likely, the continuous connection that Central America currently provides between the north and the south has been in existence for only approximately the past 3 million years, and the mountainous backbone of the region did not reach its present elevation until the latter part of the Cenozoic. This means that the variety of habitats that currently characterize the region is a rather recent phenomenon and that the ecosystems and biodiversity of Central America in general are a recent blend that has resulted from a complex paleobiogeographic history. A review of the paleobiogeographic history of the region is beyond the scope of this article. However, some salient aspects that, in addition to what we described previously, impinge on the current biodiversity of Central America include the following (**Rich and Rich, 1983**). Until approximately 3 Ma the mammalian faunas of Central America were composed predominantly of North American elements and only after this time did a north-south interchange begin with

Figure 1 Geographic location of Central America, and delimitation of the region considered in this article, including the southern part of Mexico. The Mexican portion of Central America starts at the Isthmus of Tehuantepec and includes the states of Tabasco, Chiapas, and a sector of the Yucatan Peninsula (see text for more details). Reproduced from Meffe GK and Carroll CR (1997).

a significant incursion of vertebrates from South America. It is possible that an endemic small-mammal fauna might have developed at about this time in Central America and southern North America and dispersed toward the south. The greatest affinity of Central American angiosperm (flowering plants) floras with South American ones indicates that dispersal from the south was more pronounced for plants than for animals, although Pleistocene cooling periods promoted dispersal of typically montane plants toward the south. In addition, at the height of the North American glaciation period in the Pleistocene, climatic conditions favored the dispersal of grassland- and savanna-adapted forms. Nevertheless, these ecosystems must have become as fragmented as they are today by the increasing precipitation of the latter part of this epoch. Finally, it was not until close to the end of the Pleistocene that the tropical rain forest ecosystem became widespread in Central America. This has the implications that this ecosystem, geologically speaking, is very young in the region and that its expansion decreased the effectiveness of the terrestrial connection between North and Central America. This has played a determining role in the modern composition of the biodiversity and ecosystems currently seen in Central America.

Biodiversity of Central America: An Overview

An important facet of the biodiversity of Central America is its diversity of natural ecosystems. Because of its complex geological history and intricate topography, the region of Central America includes a mosaic of ecological conditions, in which

several of the major natural ecosystems of the earth are represented. Despite the fact that the region has a restricted latitudinal range, of approximately 12° (from about 8° to 20° N), and the overall climate is of a marked tropical affinity, significant climatic variations occur due to the topographic complexity rather than to latitude. Accordingly, the ecosystems of Central America are related to three major elevational/climatic situations. The lowlands, at elevations of sea level to about 900 m, with hot climates of average temperatures of 24 °C, provide the conditions for the development of tropical forests, both seasonally dry and evergreen. The temperate zones, from about 900 to 1800 m above sea level (masl) and average temperatures of 18–24 °C, are occupied by the exuberant tropical cloud forest and temperate zone-related coniferous and broadleaf (mostly oak) forests. The highlands, from 1800 to 3400 masl and with temperatures of 12–18 °C, sustain mostly high-elevation grasslands and páramos. Superimposed to this elevational gradient, the topography and the patterns of wind circulation of the region determine the existence of marked contrasts in rainfall. The cold California current of the Pacific coast chills the air, preventing it from absorbing much water vapor from the ocean and thus reducing the chances of precipitation on this side of the region. In contrast, the easterly winds of the Atlantic coast absorb much of the moisture, which is then deposited on this side of Central America as these winds flow up and over the mountains of the region. As a result, the plains and eastern mountain slopes of the Caribbean coast receive approximately twice as much precipitation as the plains and western mountain slopes of the Pacific coast.

Such a mosaic of environmental conditions determines the existence, within a restricted geographical range, of a dramatic variety of ecosystems within a given latitudinal position. For example, within a latitudinal range of only approximately 2° and an area of approximately 51,000 km², the country of Costa Rica harbors 12 distinct life zones (vegetation types), one more than in the eastern United States, even though Costa Rica is only the size of West Virginia. This sample of ecosystems ranges from the seasonally dry tropical forests in the Guanacaste province, to the high-elevation grasslands (páramos) of the central part of the country and the wet tropical forests of the Atlantic coast. At a more local scale, a south-west–northeast transect of approximately 200 km in a straight line (i.e., not considering the ruggedness of the terrain) across the mountainous region of the state of Chiapas, in southern Mexico, harbors a collection of 12 distinct vegetation types: mangroves, palm communities, savannas, seasonally dry tropical forests, tropical moist and wet forests, cloud forests, deciduous sweet gum (i.e., *Liquidambar*)-oak forests, oak forests, pine forests, grasslands, and high-elevation grasslands.

The conglomeration of natural ecosystems present in Central America is responsible for the fact that this region contains a significant proportion of the biodiversity of the planet in terms of species richness. The mere fact that the tropical rain forest, the most diverse biome of the planet, is widely distributed in the region implies that the biodiversity of Central America is of great significance. The presence of tropical rain forest is in fact one of the distinctive criteria defining the countries of megadiversity. Another important criterion for the definition of megadiversity is the presence of coastline and the ratio of coastline to land surface. The Central American coastline is approximately 5700 km (2900 km on the Pacific coastline and 2800 km on the Caribbean side); thus, there is a coastline : surface area ratio of 0.011, which is comparable to that of some of the most important megadiversity countries. Undoubtedly, marine ecosystems and the presence of coral reefs (arguably the most species-rich marine ecosystem of Earth), including some of the most important coral reefs of

the Western Hemisphere (located on the Caribbean coast of Central America), add to the diversity of the region.

The well-established gradient of decrease in species richness with latitude implies that, overall, the tropical ecosystems of Central America are not expected to be as species-rich as their more equatorial counterparts. However, a compilation of the scattered and, most undoubtedly, incomplete information on species richness in some of the better known organisms of the region's countries, suggests that, despite its latitudinal position, species richness is outstanding (Table 1; see also INBIO's web page). The range of species richness, cumulative for plants and vertebrates, is 4270 (El Salvador) to 13,091 (Costa Rica). Furthermore, the Mexican States that form part of the region are also considerably diverse, the most notable of which is Chiapas. With an area of 73,887 km², it amounts to 5665 species of those groups. The other Mexican States, with lower values (Campeche, 1353; Quintana Roo, 1358; Tabasco, 1373), nevertheless increase the species richness of the region (CONABIO, 2008). The diversity of ecological conditions, and therefore of distinct ecosystems, dictates that the identity of species and species composition change considerably among localities within this restricted area. Thus, species turnover (or beta diversity) is likely to be very high in this region. The information available for some areas of Central America (e.g., southern Mexico) suggests that indeed this is the case. However, biological inventories are still limited and species turnover and the overall species richness of the region remain unknown. Although knowledge for some groups, primates and birds, for example, can be regarded as adequate, knowledge is particularly limited for other groups, especially invertebrates. A few isolated cases, however, suggest a significant species richness, as exemplified by the known number of species of Lepidoptera in Costa Rica, 1114 (DeVries, 1983), and 20,000, but projected to reach 40,000 species of Hymenoptera (Hanson and Gauld, 1995).

In addition to the quantitative aspects of the biodiversity of Central America, a qualitative feature deserves special consideration. This refers to the combination of floristic and

faunistic elements of the two major biogeographic zones that Central America is responsible for bringing together. This is readily noticeable in the case of flora. The elements that compose the flora of Central America belong, to a great extent, to two major floristic realms: the Arctotertiary, comprising the extra tropical territories of the Northern Hemisphere with representative genera, such as *Pinus* spp. (pines) and *Quercus* spp. (oaks), and the Neotropical, which includes the territories of tropical America, with representative genera such as *Swietenia* (caoba or mahogany) and *Cedrela* spp. (tropical cedar). Some Andean elements that belong to the paleo-oceanic realm, which comprises territories of the Andes, South America, South Africa, Australia, and New Zealand, are also represented in the Central American flora. These Andean elements include genera such as *Podocarpus* and the spectacular herbaceous plants of *Gunnera*.

The elements of the Neotropical realm are best represented in the tropical forests of the lowlands, whereas the Arctotertiary and Andean elements are predominant in the vegetation of the temperate and cold highlands. Frequently, however, there is no clear demarcation between these types of floristic elements and in several localities of Central America there is a mixture of them producing, for example, remarkable tropical rain forests at elevations of 600–900 masl, which combine the typical tall trees, lianas, palms, and tree ferns with gigantic oaks and other trees of a clearly northern affinity (e.g., *Chaetoptelea*). Conversely, some cloud forests and deciduous forests, with a predominance of Nearctic elements, may include trees of clear tropical affinity such as *Cecropia* or *Nectandra*. Another remarkable feature of the Nearctic elements of Central American forests is that several of them comprise plants characteristic of the eastern United States, with a major interruption in their distribution in Texas but that penetrate into eastern Mexico and further south into Chiapas and Central America. Some of these are taxa as representative as *Liquidambar styraciflua* (sweet gum), *Nyssa sylvatica* (black gum), and *Ostrya virginiana* (hophornbeam).

However, elements typical of the drier areas located toward the north of the Tehuantepec Isthmus are absent in the state of Chiapas (and in most of tropical Central America), but they reappear further south in the dry lands of Guatemala (Departments of Zacapa, El Progreso, and Chiquimula). This is congruent with the assumption, presented previously, that the climatic changes leading to the recent expansion of tropical rain forests must have fragmented the distribution of elements of arid and semiarid ecosystems such as the arborescent cactus *Myrtillocactus* and trees such as *Juliania adstringens* and *Apoplanesia paniculata*.

To this amalgamation of elements of tropical, temperate, and Andean affinity, an additional contingent of endemic elements must be added. Although some elements are distributed in most of Central America, others have a more restricted distribution within the region. For example, although several species and genera typical of the floras of Guatemala and Belize extend their distribution into Chiapas, other genera of the rain forests of these two countries are not present in Chiapas or any other tropical forests of Mexico. This also indicates that for a portion of the flora of Central America, the northernmost limits of distributions are Belize and northern Guatemala. However, the most important genera of trees of

the temperate and cold ecosystems of Chiapas, including *Pinus*, *Quercus*, *Liquidambar*, *Carpinus*, *Abies*, *Cupressus*, *Juniperus*, and *Taxodium*, all of which are of northern affinity, find their southernmost distribution in Guatemala or Nicaragua. The exception is the oaks, which extend well into the south, in the Colombian Andes. Likewise, several species of oak that in all probability evolved in Central American forests (e.g., *Quercus benthami*, *Quercus policaulis*, and *Quercus crispifolia*) extend their distribution into Chiapas, which is their northernmost distribution.

A final aspect related to endemism has to do with the relatively recent discovery of new taxa as a result of biological surveys and taxonomic research in the region. In the past 20 or so years, two new endemic plant families have been discovered. One, the family Ticodendraceae, is a tree from Costa Rica, and the other is a herbaceous plant in the family Lacandoniaceae from the Lacandon forests in Chiapas. The latter is a truly revolutionary plant family in which the parasitic plants lack chlorophyll and the hermaphroditic flowers present the reproductive organs in a morphological disposition which is unknown among the flowering plants (male organs in the center of the flower and female organs in the periphery).

In summary, despite the limited knowledge of the region's biodiversity, the available information provides good evidence that the biological diversity of Central America is of special planetary significance. This is not only due to its quantitative aspects (e.g., diversity of species and ecosystems) but also because of the remarkable combination of life forms of different biogeographic affinity, together with endemic elements.

Life Zones and Ecosystems

The most synthetic and revealing way of describing the ecosystems of Central America is through the description of the vegetation, since it is the most obvious physiognomic descriptor of the ecosystem, is the base of the food chain, and provides the structural matrix on which most communities and populations of animals live or indirectly depend on.

A very popular classification system is widely used to describe the ecosystems of Central America. The system, based on the life zone concept elaborated by Holdridge (1967), combines three climatic characteristics of a given region – temperature, precipitation, and an index of the availability of moisture, potential evapotranspiration, as a predictive model to forecast a corresponding vegetation type, or life zone. Although the Holdridge system is widely used, particularly in Costa Rica, the classification system developed by Miranda and Hernández-X (1963) is the one most used for the Mexican vegetation. This system is based on the physiognomy (i.e., the appearance: life forms and height) and phenological character (e.g., whether the predominant plants are deciduous or evergreen) of the vegetation. The conceptual basis for this system is that vegetation physiognomy reflects the adaptive response of plants to the environmental characteristics where vegetation develops. Given the facts that these two systems do not coincide in vegetation nomenclature and the number of ecosystem types resulting from both is very large and detailed, we use here a system that attempts to capture the essential aspects

of the two systems and provides a more simplified classification. In addition, this simplified system attempts to present a nomenclature that is comparable to that used more generally in the literature.

Tropical Rain Forests

The most distinctive aspect of this type of forest in Central America is, as in other regions, their great diversity of species. For example, the Lacandon forest of Chiapas includes approximately 4300 plant species, and the La Selva field station in Costa Rica harbors 1500 plant species and approximately 411 species of birds, 116 species of mammals, and 479 species of butterflies (McDade *et al.*, 1994).

Regarding physiognomy and structure, these forests are characterized by the presence of very tall trees (30–50 m) and by their evergreen vegetation – most of the plants retain their leaves year-round. Most of the trunks of the large trees, besides being straight, have diameters at breast height of between 30 and 150 cm. However, a few, such as the *Ceiba* trees, can have even thicker trunks and their height can reach beyond the forest canopy. Another distinctive feature of these forests is the presence of irregular or undulating contours of the tree trunks of many species, particularly at the base, where they become extended protrusions, approximately triangular in profile, which may play the role of support for the tree. The structures, called buttresses, can adopt several shapes or designs that can often serve as distinctive characteristics of particular species. The bark on the trunks, in general, is either smooth or scaly, with color ranging from light tones in some figs, to dark ones in the mahogany tree and shiny reddish hues in the gumbo-limbo (*Bursera*).

Even when not clearly defined, from the canopy down, there is a succession of layers of vegetation (stratification), from the subcanopy to the understory, with a spectacular profusion of life forms. The understory includes a layer of plants, most notably short palms, from less than 1 m up to 8 m. At ground level, the undergrowth is composed of ferns, several herbaceous plants such as gingers, some trailing plants, and the saplings or seedlings of the species found at higher levels.

A direct consequence of this stratification and profusion of plants is that light diminishes from the top down to ground level, where only 1–5% of the available light reaches through. Such limited light availability leads to spectacular morphological and functional adaptations in the plants to compensate for the limitation of this critical resource. Such adaptations are in turn responsible for the existence of other physiognomic and structural features of the forest, including the occurrence of a great variety of climbing plants, both woody (lianas) and herbaceous (vines, mainly in the family Araceae), together with a variety of epiphytic plants (i.e., plants that live on top of other plants). By far, lianas are the most conspicuous climbers since they can reach over 50 cm in girth and, depending on the locality, they can contribute one to three of every 10 trunks. In Central America, even some species of palms have evolved the habit of liana, as is the case of *Desmoncus* spp. and *Chamaedorea elatior*. The Araceae provide the most notable example of nonwoody climbers, not only

because they cover the trunks of the trees on which they climb and their abundance on the canopy, but also because of their abundance as trailing plants at ground level, where they spread in search of trunks to climb. Vascular epiphytes, the most evident of which are the orchids, constitute a significant component of the biodiversity, given that the orchid family is commonly the most species-rich family in Central American forests. In addition to orchids, bromeliads constitute another important element of the epiphytic life form of these forests. Although bromeliads are not as specious, they are very abundant so that these two families constitute one of the most distinctive features of the physiognomy of Central American rain forests.

A much less conventional type of climbing plant is that of the hemiepiphytic trees, represented chiefly by the strangler figs, which also constitute a distinctive feature of these forests. Stranglers germinate and take root on the branches of other large trees and then grow downward at an impressive rate, producing many strong trunks that hold on to the ground while covering the tree on which are established, forming a strangling network that eventually kills the initial support tree.

In addition to this diversity of morphological adaptations, most woody plants of the tropical rain forest have a series of ecological and functional attributes that allow them to deal with the problem of light limitation. Such attributes comprise adaptations that fit the dynamic nature of the tropical rain forest. In essence, the winds that occur in these regions, particularly during the rainiest season and winter months (November–February), overturn one or more of the giant trees of the canopy, creating so-called light gaps of up to 800 m². Depending on the locality, the incidence of such gap formation can be very intense, ranging from turnover rates (i.e., the number of years elapsed between two successive gaps) of 60 (e.g., in some Mexican forests) to 100 (e.g., in some Costa Rican Forests) years. The result is the production of natural clearings with high light availability and higher temperature than in the shady understory. Many plant species produce dormant seeds equipped with photosensitive mechanisms that allow them to detect the amount and type of light of the clearing and germinate in these conditions. This type of plant constitutes the group of the pioneer species, the most representative of which are *Cecropia* spp. and *Ochroma*, the balsa tree. Pioneer species display a very rapid growth and recolonize gaps by growing together with some of the young plants of the typical shade-tolerant species of the mature forest that might have been growing in the understory. The gap gradually begins to close, and is colonized by other species adapted to increasing levels of shading. These conditions make it impossible for the survival of the pioneer species that did not manage to grow and reproduce on time. The shade-tolerant species, provided with morphological, physiological, and growth mechanisms suited to scarce illumination, make their way to the canopy. This process of opening and closure of the forest creates a dynamic mosaic of vegetation with varying degrees of regeneration. In the tropical rain forests of Central America the mature phase is predominant and the most representative of the described physiognomy. In addition, in this phase, the leaves of the plants are predominantly dark green and sometimes shiny on the upper surfaces, tough in texture, and with sizes that range from medium

(5–10 cm in length) to large (up to 1 m or more). As in other tropical rain forests, leaves have tapering extensions on their tips, which are thought to serve to drain off the excess of water. Colorful, fleshy fruits are very abundant in the plants of the mature forest, but flowers tend to be mostly small and there is a predominance of light shades of white and green; bright and shiny colors are less abundant.

The complex and diverse vegetation serves as a matrix in which a highly diverse fauna is found, particularly insects. Given the great diversity of plants and animals, a distinctive aspect of these forests is the complex network of interactions among different species, particularly between plants and animals: pollination, dispersal (the transportation of fruits and seeds by animals), and herbivory (the consumption of plant tissue by animals). As a result, the shapes, colors, and scents of flowers and fruits and seeds, and a wealth of toxic or attractive substances, determine the behavior, feeding, and sensory patterns of animals. These animals defoliate, seek out seeds, consume nectar and other fluids, guard and defend plants against herbivores, and even attempt to copulate with orchids that resemble and smell like female bees.

Seasonally Dry Tropical Forests

Located at altitudes from sea level up to 1500 m, this kind of forest is characterized by a long dry period (from 4 to 6 months). As a result, physiognomically, they are typified by the deciduous nature of their vegetation: Green and luxuriant in the rainy season and grayish and leafless when it is dry. The highest trees rarely exceed 25 m, and the dominant flora comprises smaller trees, shrubs, and long-branching trees, although vines are also found. Commonly, two vegetation strata can be defined: the canopy, with trees 15–25 m tall, and the understory, with shrubs and treelets 5–15 m tall. The ground layer is sparse in general. The scarcity of vines and epiphytes is notable, although they can be found in microhabitats with favorable conditions and along riverbeds. Some epiphytes, such as bromeliads, can be found in abundance on trees growing on some suitable slopes. Another typical feature of these forests is the presence of numerous lichens attached to the branches of trees and shrubs which acquire the colors of these lichens. In general, most woody plants have relatively small diameters, except in areas with greater soil moisture, such as in the vicinity of permanent or semipermanent bodies of water. As a consequence, Central American dry forests present two characteristic physiognomies: The seasonally deciduous forest associated with the hills, which is the most widespread type, and the riparian forest, smaller in extent, with larger trees that do not shed their leaves during the dry season. Frequently, riparian sectors of the dry forests include species of trees that are typically present in evergreen forests, including several large figs. In addition to these two major variants of the dry forest, in rocky outcrops or as they extend into even drier climates or toward their northernmost distribution in Mexico, average tree height decreases and there is an increased presence of spiny plants, mainly of the legume and cactus families. Another major distinctive feature of the trees in these forests is their bark, which in many species is smooth and shiny and frequently exfoliating (i.e., it peels off), as is the

case of *Jatropha* or *Bursera*. In addition, several species present prominent thorns, as is the case of several members of the Bombacaceae family (*Ceiba* and *Bombacopsis*). Another distinctive aspect of the Central American dry forests is the abundance of species with small leaves, frequently of less than 5 cm in length, and many of the species present divided leaves composed of leaflets, although plants with entire or undivided leaves are also common. Several members of the legume family are representative of species with divided leaves. In addition, in marked contrast to the rain forest, dry forest plants typically present showy flowers, and many of the species produce their flowers in remarkable synchrony, particularly during the dry season when leaves are absent. These reproductive and vegetative rhythms are the norm among the plants of these forests, but notable exceptions occur, the most spectacular of which are those related to the patterns of leafing out. Although some species keep their leaves during the dry season, others such as *Jacquinia nervosa* do not merely maintain their foliage during the harsh season but also lose it during the rainy season. The reasons for this leafing pattern are not fully understood by ecologists. Likewise, several species do not flower in mass or otherwise during the season of drought but rather at other times, a remarkable example of which is the *Ipomoea* tree.

The presence of endemic taxa in tropical dry forests is particularly high in these forests. Endemic taxa in Central American forests include species and genera of a marked affinity with the dry lands of northern Mexico. In addition, at least one endemic life form is known to the tropical dry forests of Mexico – the *Ipomoea* tree referred to previously. This remarkable species is a member of the morning glory family, but one that has evolved as an arborescent, not a vine, life form.

In stark contrast with the rain forest, dry forests have been studied to a much poorer extent throughout Central America. Nevertheless, the only available reviews of this type of forest (Bullock *et al.*, 1995; Dirzo *et al.*, 2011) suggest that at least some aspects of the ecological complexity of these ecosystems are comparable to those of their rainy counterparts. Many complex plant–herbivore interactions, for example, are the same as those known for rain forests. Some of them, such as the famous mutualistic interaction between the bull's thorn *Acacia* shrubs/trees and their defending *Pseudomyrmex* ants, can be even more prominent in dry forests. In this remarkable interaction, the plants provide a home (the bull's thorns) and food (sugar produced in extrafloral nectaries and specialized, lipid-rich structures) for the ants. These, in turn, are very aggressive and attack potential herbivores of the plant and even remove the vegetation in the immediate vicinity of the plant, thus avoiding potential competition.

Tropical Cloud Forests

Although with considerable variation depending on the locality, elevation, and aspect, these forests owe their physiognomy, in general, to their enormous trees. Although not very rich in species, this group of trees is very abundant. Some of these may exceed 50 m, with trunks of up to 2 m in diameter at breast height, such as is the case of some oaks and the spectacular *Talauma mexicana* in the cloud forests of

Chiapas. In the mature forest areas the cloud forest is clearly dominated by woody plants. Among these, the lianas, although not completely absent, are considerably scarce. A few of the trees lose their leaves during the driest time of the year, but because a high proportion of the trees do not lose their foliage or, if they lose it, they replace it very quickly, the forest as a whole can be regarded as an evergreen ecosystem. Although the cloud forests located in the southern parts of Central America are dominated by species of tropical affinity, toward their northern distribution, particularly in Chiapas, elements of boreal affinity become prevalent and intermingle with the tropical elements. This is the case for the oaks (e.g., *Quercus candicans* or *Quercus skinnerii*) and especially for the sweet gum tree *L. styraciflua*. This noticeable tree extends in the Central American cloud forests from Honduras to Chiapas. Although the dominant trees of the more southern forests, such as in Costa Rica, are taller, and a stratification is more clearly defined than in their more northern counterparts, the rest of the physiognomic characteristics are very similar. Although buttresses are present, they are not as developed as in the tropical rain forest trees. The understory and lower strata of the cloud forest are notable for the great profusion of palms and ferns, the most conspicuous of which are the spectacular tree ferns. In some areas these can reach up to 20 m. The ferns, including smaller species, tree ferns, and their immature forms, achieve a degree of abundance in the cloud forests that is hardly comparable to that of any other Central American ecosystem. Understory trees can be 8–15 m tall and frequently have leaning, crooked trunks and relatively long crowns. The shrub layer is fairly dense and can reach 2 or 3 m. The ground layer is considerably covered by ferns, *Selaginella*, and several broad-leaved herbs. Bluish coloration in several plants of these lower strata is quite common. Another distinctive feature of these forests is the great profusion of epiphytes and semi-epiphytic plants. Most of the trees are covered by dense associations of ferns, moss, orchids, bromeliads, peperomias, herbaceous vines, and other vascular plants such as the gesneriads. A spectacular fauna of characteristic birds, including quetzals, tanagers, and horned guans, accompanies such variety of plants.

Throughout Central America, this type of forest is of a very restricted extension and patchy distribution. As a result, and because of the relatively poor knowledge of its ecology and also because of its crucial role in retaining water, this Central American ecosystem requires attention and formal protection before it is converted into plantations and grasslands.

Mangrove Forest

Although geographically widespread, mangrove forests are locally restricted to coastal areas, called estuaries, where fresh water meets marine water and salinity is high. This demands the presence of plant species that are tolerant of high levels of salinity: the mangrove trees, which are the dominant species of these ecosystems. In Central America mangroves grow on the Caribbean, Pacific and Atlantic coasts, with the greatest coverage in Panama (174,435 ha), Honduras (78,668 ha), and Belize (78,511 ha) (FAO, 2007). Only a few tree species occupy these forests, typically three, with the richest localities reaching

up to nine species. The overall physiognomy of these forests varies locally ranging from 40 m tall forests in areas of high precipitation such as Panama, Belize and several localities of Mexico, to 1.5 m in Nicoya, Costa Rica, where precipitation is low. Mangroves can be considered as a keystone ecosystem given the significant provision of environmental services they provide. Such services include their role as nurseries and refuge for marine and terrestrial wildlife and, most noticeably, their role in protecting the coastline against the effects of tides, storms and tsunamis.

Temperate Forests

Temperate-like forests of Central America include two major types (oak forest and pine forest), but in some parts, in which the dominant species overlap, a mixed oak–pine forest can be distinguished. Oak forests range from the tropical montane and premontane forest dominated by *Quercus* spp. and Lauraceae in Costa Rica, to the clearly oak-dominated forests (encinar) of Chiapas, Mexico. The Costa Rican oak forests are evergreen communities of low to intermediate height, with trees 20–25 m tall and unbuttressed trunks and rough bark. The understory is open, with trees 4–15 m tall and with slender trunks and highly ramified crowns. The branches and trunks of trees are heavily covered with herbaceous epiphytes and moss. The oak forests are best represented in Chiapas, where they form distinct associations ranging from woodlands intermingled with tropical rain forest (with *Quercus oocarpa*) or cloud forest (*Q. candicans* and *Q. skinnerii*), to dense monodominated oak forests at elevations of approximately 3000 m, with trees 35 m in height (*Quercus acatenanguensis*). The most widespread oak forests of Chiapas are those of intermediate elevations (700–2500 masl). In the drier areas near the central depression of the state, these are low forests with grasses in the understory and they are sometimes adjacent to seasonally dry forests and savannas. In contrast, in areas of higher elevation and where winds are still loaded with water vapor, they are similar to cloud forests: dense, and loaded with epiphytes, particularly bromeliads and orchids. The most impressive forests of this type are those near the spectacular Montebello Lagoons. Other associations include the low oak forest of 2–4 m in height, which resembles a chaparral, near the city of Comitán.

The pine forests have their greatest distribution in the territory of Chiapas and extend, more sparsely and with fewer associations and diversity, toward the south to Honduras. With the exception of some fragmentary information for the pine forests of Chiapas, these Central American ecosystems are very poorly known scientifically. In Chiapas, these forests occupy most of the surface of temperate and cold areas, to which pines are very well adapted. This is due to the reduced surface of their leaves (needles), which are also well protected on their surface, allowing them to resist long periods of drought and low temperatures. In addition, the resin present in these plants' tissue provides resistance to several pests and the thick bark of the trunk and branches help to reduce the effects of fire. In general, these forests are dominated by one or a few tree species. They extend from intermediate elevations up to the timberline, and where rainfall does not exceed

1200 mm y⁻¹. However, even in areas of more precipitation, pine forests can be occupied by species with thin and flexible needles (*Pinus strobus* and *Pinus ayacahuite*). The most widespread pine forests, at elevations of 750–3000 m, are dominated by *Pinus oocarpa*, whereas *Pinus hartwegii* and *Pinus rudis* dominate the more restricted pine forests of the coldest regions (at elevations of 2900–4000 m).

In most cases, the understory is dominated by dense grassland. A significant, although seldom considered, aspect of the biodiversity of both oak and pine forests is the presence of a rich flora of shrubs and herbs, many of northern affinity but including several species endemic to these ecosystems.

This variety of Central American oak and pine forests, of peculiar and restricted distribution, is very poorly studied ecologically and from a biodiversity point of view, but these forests are disappearing at alarming rates, and most of what remains is heavily fragmented. It is likely that some significant aspects of their ecology and biodiversity have been very strongly disrupted or lost.

Other High-Elevation Ecosystems

Two distinct ecosystems are present at the highest elevations in Central America: the páramo and the high-elevation grassland or zacatonal. The latter is an association of tall and dense grasses that extend in the clearings of pine and oak forests of the highest elevations. This indicates that their current extension is most likely secondary; that is, derived from human perturbation due to the considerable resistance of the grasses to the fires that sweep these regions. The height of these systems is 0.5–2 m and the dominant grasses include *Epicampes macrura*, *Festuca amplissima*, and *Stipa ichu*. The Central American páramo is the northernmost occurrence of the Andean páramo. In Costa Rica it is dominated by shrubs where drainage is adequate and by bogs where drainage is poor. Another portion of páramo occurs in Chiapas, at elevations of 4000 m or higher (above the timberline of the Tacaná Volcano), where it is physiognomically similar to the zacatonal but the dominant grasses (*Calamagrostis* and *Festuca*) are shorter, sometimes forming a prairie. Frequently, the distance among grasses is considerable and there is much open space for the establishment of other plants, many of which barely rise above the level of the ground. This group of plants includes several members of the rose (*Alchemilla* and *Potentilla*), daisy (*Senecio* and *Gnaphalium*), and cabbage (*Draba*) families. The small size and prostrate habit of the plants of this ecosystem are advantageous. They are able to take advantage of the heat in the layer of air close to the ground during daylight since the higher layers, even during daylight, are extremely cold and incompatible with their functioning and survival.

Central American Ecosystems in Light of Global Environmental Change

Several aspects of global environmental change are predicted to have a profound effect on the biodiversity of the planet. Among these, climatic change has received the greatest attention, but recent information indicates that, in addition, the current

patterns of land use (leading to deforestation and habitat fragmentation) may significantly affect biodiversity. Although information is limited, particularly for this region, it is of interest to review the available models and the information regarding the situation of Central American ecosystems in the light of climatic change and land-use patterns.

Climatic Change

General circulation models have been developed to forecast the changes in temperature and rainfall and their geographic variation under a given set of assumptions, mostly related to CO₂ concentrations. These models suggest that the greatest changes of climate are to be expected at higher latitudes. Consequently, given the relatively low latitude of Central America, it could be expected that the natural ecosystems of this region would be affected to a minor degree. Indeed, the maps resulting from these models depict Central America as a region of relatively minor climatic change. Although this is an optimistic result, it is important to bear in mind that such maps and forecasts are, by necessity, of very gross resolution. Unfortunately, no detailed analyses are available to assess the situation at a finer geographical scale. The IPCC report for 2007 (Christensen *et al.*, 2007) suggests that for the Central America region (including Mexico), annual precipitation is likely to decrease in most of the region. The multimodel data set models suggest a general decrease in precipitation over most of Central America, and the median annual change by the end of the twenty-first century is projected to be –9% under the A1B scenario (temperature rise of 2.8 °C, range 1.7–4.4 °C, and sea level rise likely range 21–48 cm). Likewise the report suggests that the projected precipitation decrease will be accompanied by more frequent dry extremes in all seasons.

A local study on the expected changes in vegetation coverage resulting from climatic change in the forests of Mexico (Villers and Trejo, 1998) provides some useful insights, given that the study included the northern part of Central America. In addition, the study considered the major Central American ecosystems described previously. In synthesis, the results show that, in comparison to their current potential distribution, tropical forests of the warm lowlands would be the least affected: Seasonally dry forests are expected to remain about the same, whereas rain forests are even predicted to increase. In contrast, temperate forests appear to be affected the most: Pine forests are predicted to disappear, whereas cloud forests would experience reductions of 45–75%. In summary, whereas global models forecast little climate change impact on the ecosystems of the region, more detailed models suggest that this is likely the case for the tropical ecosystems of the warm/lowland climates but the temperate ecosystems are expected to be significantly impacted.

Land Use Change

The best available descriptive index of the patterns of land use is the rate of deforestation. Deforestation rates are available from the FAO annual reports, which include data for regions and the globe at large (Figure 2a), as well as countries,

Figure 2 The estimated rate of deforestation (% forest area lost per year) in Central America (CAM) in the context of other regions of the world, including South America (SAM), Africa (AFR), Oceania (OCE) and the overall estimate for the world (a), and annual deforestation rate in six Central American countries (b). Data from Food and Agriculture Organization (FAO) (2011) *State of the World's Forests*. Rome: Food and Agriculture Organization of the United Nations. Codes for the countries are given in Table 1. Numbers in parentheses above each bar indicate absolute deforestation rates ($\text{ha} \times 1000$).

including Central American ones (Figure 2b) (FAO, 2011). In a global and regional context (Figure 2a) the statistics indicate that although in absolute terms deforestation in the Central American region, for the period 2000–2010 was low ($248,000 \text{ ha y}^{-1}$), yet its proportional rate of deforestation was 2.4 times higher than that of South America and Africa, and 12 times higher than the global rate. Within the region (Figure 2b), there is considerable variation among countries, with the highest rates in Honduras and Nicaragua, and the lowest in Belize and Panama, and with El Salvador and Guatemala in the middle. The situation in Costa Rica is particularly revealing, given that it is a country that has made a significant effort to conserve its natural ecosystems. While studies from the 1980s to early 1990s indicate that most of the country's ecosystems were heavily deforested, with percentages of area of habitat lost ranging from 32 (montane rain forest) to more than 90 (dry deciduous forest, lowland moist forest, premontane moist forest, and lower montane moist forest), national deforestation rate decreased to 0.8% in the period 1990–2000 and in the period 2000–2010 it actually became a positive change, with 23,000 ha of forest regrowth.

In the case of Mexico, studies on deforestation in the tropical rain forest of Lacandonia, Chiapas (Mendoza and Dirzo, 1999) show a considerable degree of variation in deforestation rates among localities, with a range of 0–8% and an average of 1.6% per year. Even if these values seem low, the estimated absolute deforestation rate for this area is 6286 ha y^{-1} .

Finally, it is worth considering the deforestation trajectories of mangrove forests in Central America, given their special ecological and ecosystem services importance (described above). While these forests have been dramatically impacted throughout Central America, recent proportional deforestation rates are relatively low, ranging from zero (Guatemala, Nicaragua), to 0.1–0.5 (Belize, El Salvador, Costa Rica, and Panama), to an extreme $3.1\% \text{ y}^{-1}$ (Honduras). With the exception of Honduras, the low deforestation rates in the rest of the countries are indicative of the fact that some areas are being protected from anthropogenic impact, and other areas have been impacted to the extent that only the most inaccessible areas remain susceptible to being deforested.

In synthesis, the information presented in this section indicates that even if climatic change will have a moderate impact on the ecosystems of Central America, forests of all types seem to be seriously threatened by the current patterns of land use. Moreover, the available information suggests that such patterns of land use exacerbate the negative effects of climatic change. Finally, the current patterns of land use and the expected effects of climatic change on the temperate forests might have a significant effect on the functioning of the ecosystems and overall structure and composition of the biodiversity of Central America. The relevant information to assess the consequences of the loss or degradation of the Central American ecosystems is very limited and is beyond the scope of this article. Nevertheless, our knowledge of their biodiversity and the threats they are currently experiencing indicates that a significant effort toward their conservation and wise management is a major agenda for the scientific community and society at large.

Glossary

Accretionary Accumulating sand.

Dissipative beaches Wide, flat beaches.

Effluent line Level on the beach face where the water table intersects the surface.

Macrotidal Describing a spring tide range of more than 4 m.

Microtidal Describing a spring tide range of less than 2 m.

Morphodynamics Interactions between the physical structure and the water and sediment movement in a beach and surf zone environment.

Psammophilic Sand-loving.

Reflective beaches Narrow, steep beaches.

Supralittoral Immediately above the intertidal zone.

Transect A linear series of samples, for example, across the intertidal zone.

Introduction

Sandy beaches dominate the ocean shorelines of all temperate and tropical continental coasts. These ecosystems are devoid of any biological structures and their morphology and dynamics can be defined in terms of three interacting factors: tides, waves, and sand particle size. Although still less studied than most other coastal systems, beaches in the new millennium are much better characterized. A significant body of knowledge has accumulated and beach studies have become increasingly theory driven. Here we describe the global range of wave-exposed, sandy beach types that can occur in response to changes in waves, tides, and sand. We also summarize the current ecological status for sandy beach macrofauna, focusing on key processes operating on different scales and how they interact to yield the patterns observed by ecologists.

Sandy Beach Types

Ocean beaches are defined by the interactions between tidal regimes, the wave energy they experience and the nature of the sand available for sorting and transport by the tides and waves. These interactions produce a range of beach morphodynamic types which span a continuum from microtidal reflective beaches, narrow and steep, to macrotidal dissipative systems, which are wide and flat and, under conditions of large tides, grade into tidal flats (Short, 1996). The simplest overall index of beach state is the beach slope, which is a product of the interaction among all three of these variables: beach face slopes flatten as wave energy increases, tide range increases or particle size decreases, if other factors are kept constant. Thus the flattest beaches occur in macrotidal regions of high wave energy and fine sand, and the steepest beaches occur in microtidal regions with low wave energy and coarse sand. A range of beach morphodynamic types can be distinguished between these extremes.

In microtidal regimes, where beaches are wave dominated, three beach states can be recognized: reflective, intermediate, and dissipative. The reflective beach, characterized by a steep face and absence of a surf zone, occurs under a combination of coarse sand and gentle waves. The shoreward transport of sand, which occurs under these conditions, causes all sediment to be stored on the subaerial beach face; the reflective beach thus represents the accretionary extreme in beach states. Here, waves surge up the beach face, where they may break before being reflected back to sea (Figure 1). Dissipative beaches, in contrast, are a product of large waves moving over fine sand. This results in a flat beach face and wide surf zone. Waves break far out and dissipate their energy while traversing the surf zone as bores before expiring as swash on the beach face. Dissipative beaches, with their sand spread out over extensive surf zones, thus represent the erosional extreme in beach states. Between these two extremes, intermediate beaches are distinguished by the presence of surf zones smaller (20–100 m wide) than in the dissipative situation. The intermediate surf zone has well-developed bars (sandbanks) and channels with rip currents (see Figure 1).

Beaches are not locked into a single morphodynamic state and respond to changes in wave energy by moving towards dissipative conditions during storms (and spring tides) and towards reflective conditions during calm weather (and neap tides); thus, sand erodes or accretes on the beach face as wave height (and tide range) rises or drops. Dean's parameter (Ω), also known as the dimensionless fall velocity, is a useful index that describes the state of a microtidal beach, that is, the extent to which wave energy is dissipated or reflected:

$$\Omega = \frac{H_b}{W_s \cdot T}$$

where wave energy is given by modal breaker height (H_b , cm) divided by modal wave period (T , seconds) and sand fall velocity is the sinking rate (W_s , cm s^{-1}) of the mean sand particle size on the beach. Ω values < 2 characterize reflective beaches, whereas $\Omega > 5$ define dissipative ones and $2 < \Omega < 5$ characterize intermediate beach states.

Figure 1 Three morphodynamic states of microtidal beaches (HT: high tide, LT: low tide).

The foregoing description of beach types adequately covers most microtidal situations, but increasing tide range tends to make beaches even more dissipative, because it allows the surf zone to work back and forth over a wider area (Short, 1996). Indeed, fully reflective beaches will not occur when tide range exceeds 1–1.5 m. On beaches with larger tides, reflective conditions can only occur at the top of the shore, between the neap and spring high-water swash lines: this area is reached by swash (but not surf), it is controlled by swash processes and is accretionary and steep, in contrast to the rest of the shore, where shoaling and breaking wave and bore processes operate.

Beaches are generally tide dominated under large tidal regimes (mean spring range >4 m), whereas in intermediate situations (tide range 2–4 m) they are mixed and either waves or tides can dominate. A useful index of the relative importance of waves and tides is the relative tide range (RTR), given by the mean spring tide range divided by the modal breaker height. By combining Ω and RTR, a two-dimensional model of beach states can be produced (Figure 2).

Ecologists have developed various indices as simple measures of overall beach state. Among these is the beach index (BI, McLachlan and Dorvlo, 2005), which can be used to compare beaches of differing tide range:

$$BI = \log_{10} \left(\frac{M_z \cdot TR}{S} \right)$$

where M_z is the mean grain size (in phi units +1, to avoid negative values), TR is the maximum spring tide range (m) and S is beach face slope (dimensionless). BI ranges

0–4, with values <1.5 representing microtidal reflective beaches and values >3 representing macrotidal dissipative beaches.

Sampling Beach Macrofauna

Community studies of beach macrofauna make use of standard beach transect surveys. These typically involve quantitative sampling across the intertidal zone by excavating quadrats and passing the sand through a screen of 0.5- or 1-mm mesh. The finer mesh size is more effective in sampling larval stages of macrofauna and some larger meiofauna, but is not practical where sand is coarse. Besides quadrat sampling, pitfall traps have been used to sample the supralittoral fauna. These are less quantitative but useful for collecting sparse fauna that move over large areas. In transect sampling, beaches are compared as if they were units, each transect survey representing one datum point. Species richness in beach surveys is summed for all samples in a transect and abundance is usually calculated per running meter of transect, so results are expressed as the number of species per transect and the number of individuals per linear meter of transect (ind m^{-1}), which can be estimated as follows:

$$IST_r = \frac{\sum_{i=1}^n q_i}{n_r} w_r$$

where the mean density q ($\text{ind} \cdot \text{m}^{-2}$ or g m^{-2}) of all n samples pertaining to transect r is multiplied by the corresponding width (w) of the species distribution across the beach. This equation is used to avoid biased results from using mean

Figure 2 Two-dimensional model of beach states. Reproduced from Short AD (1996) The role of wave height, period, slope, tide range and embaymentisation in beach classification: A review. *Revista Chilena de Historia Natural* 69: 589–604. Distances are in meters.

density per quadrat ($\text{ind} \cdot \text{m}^{-2}$) as an abundance estimate, after which beach profiles have been impacted during either rough or calm conditions. Despite the above, density estimates are still being used in sandy beach ecology.

The width of sandy beaches ranges from as little as 10 m in reflective, microtidal situations to hundreds of meters in dissipative tidal flats, thus representing an order of magnitude range in the length of an intertidal transect. The total area sampled per transect (assessed as total area excavated, i.e., levels $\times$ replicates $\times$ quadrat size), however, has fallen within a much smaller range ($2\text{--}4.5 \text{ m}^2$), with most cases being around 3 m^2 . A total sampling effort per beach $< 2 \text{ m}^2$ introduces problems of undersampling (Jaramillo *et al.*, 1995) and species–area curves (Figure 3) indicate that a sample area of 3 m^2 recovers 90% of the species on microtidal beaches but would result in serious undersampling on wider beaches, such as macrotidal flats. Simulation and field studies indicate that sampling 4 m^2 of sediment from three systematic across-shore transects is sufficient for intermediate beaches, which are the most common morphodynamic type globally (Schoeman *et al.*, 2008).

Two different sampling designs are usually conducted on sandy beaches (Defeo and Rueda, 2002): (1) species driven and (2) environmentally driven. In the former, sampling points are systematically allocated along transects perpendicular to the shoreline to cover the entire across-shore distribution of the species; at least two quadrats with zero abundances are sampled in both the upshore and downshore directions before terminating a transect. The second sampling procedure is also based on shore-normal transects, with quadrats randomly allocated at fixed beach levels defined by the position of reference points, such as tidal marks (meso-/macrotidal beaches), swash levels (microtidal beaches), or drift and effluent lines. The validity of this sampling design

Figure 3 Species/area curves for sandy beach macrofauna. Reproduced from Jaramillo E, McLachlan A, and Dugan J (1995) The species/area relationship on sandy beaches. *Marine Ecology Progress Series* 119: 311–314.

has been questioned, because short- (hours, days) and medium- (seasons) term variations in macrofauna distribution might not necessarily follow swash levels or effluent or drift line positions (James and Fairweather, 1996; Brazeiro and Defeo, 1996). This diminishes the applicability of an environmentally driven sampling design defined by *a priori* fixed strata. A full discussion of sampling issues in sandy beaches is presented in Schoeman *et al.* (2008).

General Patterns

Macroscale

Latitudinal Trends

Species richness on sandy beaches increases from temperate to tropical regions for beaches of similar types (Figure 4). Comparison of latitudinal trends in species richness using beach face slope as covariate (ANCOVA, with slope log-transformed to fulfill statistical assumptions), shows that, for the same slope, the number of species is significantly greater for the tropics than for the subtropical, warm temperate and cold temperate zones. However, abundance and biomass tended to increase from tropical to temperate beaches, although these trends are less clear for polychaetes and molluscs than for crustaceans (McLachlan and Dorvlo, 2005).

Greater abundance and biomass on temperate dissipative beaches could be attributed to greater food availability, due to greater productivity. The presence of surf diatom blooms has led to the definition of temperate dissipative beaches as semiclosed ecosystems, in contrast to reflective beaches, defined as interfaces with low productivity, subsidized by organic inputs from the sea (McLachlan and Brown, 2006). Although increased wave energy in temperate areas seems to cause increased productivity and biomass, stranded seagrass or algae

(Colombini and Chelazzi, 2003), or the presence of upwelling can also add to sand beach energetics and thus biomass.

Morphodynamic Effects

Species richness increases in response to increasing tide range, increasing wave energy, decreasing sand particle size and in flatter and wider beaches. This means that macrofaunal species richness increases as beaches become more dissipative (McLachlan and Dorvlo, 2005). For ocean beaches, the number of species recorded in a single transect survey ranges from 1 to 40 (if insects are excluded). More dissipative beaches and flats may harbor 20–40 species at least, as the shore flattens towards the dissipative or tidal flat extreme.

The best models fitted to 194 beaches based on data from five continents shows that the relationships between species richness and morphodynamic features of beach type are not linear. Summarizing global trends for a diverse range of exposed sandy beaches, Figure 5 shows that species richness: (1) increases asymptotically from reflective to dissipative beaches (Figure 5(a)), with increasing tide range (Figure 5(f)), and with a measure of intertidal area obtained by dividing tide range by the beach face slope (Figure 5(e)); and (2) decreases exponentially with increasing sand particle size (Figure 5(c)) and slope (Figure 5(d)). Moreover, species richness increases linearly with the Beach Index (Figure 5(b)), i.e. from microtidal reflective to macrotidal dissipative beaches.

Following the same trend as for species richness, macrofaunal abundance and biomass decrease exponentially with increasing sand particle size and slope (Figure 6). Thus, species richness in sandy beaches increases from microtidal reflective to macrotidal dissipative conditions, whereas abundance and biomass increase exponentially, leading to greater densities of organisms.

Figure 4 Latitudinal trends in species richness (excluding insects), based on 194 beaches in 10 countries using beach face slope as covariate. The model fitted for all the four regions ($Y = a + b \cdot \log X$) was highly significant ($p < 0.001$).

Figure 5 Global patterns of species richness on sandy beaches from five continents ($n=194$). Relationships between species richness and (a) Dean's parameter Ω ; (b) Beach Index; (c) grain size; (d) beach face slope; (e) the composite index Area; and (f) tide range. All models included in each panel were highly significant ($p < 0.001$).

Mesoscale: Zonation and Alongshore Distribution

The mesoscale concerns variations within a single beach, i.e., an uninterrupted sandy shore, both in the alongshore and across-shore directions (Defeo and McLachlan, 2005). The intertidal macrofauna of ocean sandy beaches is usually dominated by crustaceans, molluscs, and polychaetes, with other groups, such as insects, nemertean worms, echinoderms, anemones, and fishes, being of minor importance or restricted to the extreme upper or lower beach levels. Crustaceans tend to be most successful in reflective conditions, where their great mobility enables them to cope with turbulence. Among the crustaceans, ocypodid crabs, hippid crabs, cirrolanid isopods, a variety of amphipods, and psammophilic mysids are the most typical. Molluscs, both gastropods and bivalves, are successful over a wide range of beaches. Clams, in particular, may form large populations on high-energy dissipative beaches, where

they can support commercial fisheries. Polychaetes are the group that is most sensitive to beach state and are absent or scarce on reflective or coarse sand beaches. On low-energy shores of fine sand, polychaetes can be particularly abundant and include predator/scavengers, deposit, and suspension feeders.

Sandy beach populations and communities exhibit a well-defined structure with significant across- and alongshore variations. Macrofaunal species tend to be aggregated in elliptical patches from m to km, with the major axis parallel to the shore, and varying according to the different susceptibility of each species and year group (i.e., recruits vs. adults) to environmental factors (Defeo and McLachlan, 2005). In this setting, sandy beaches display zonation of their macrofauna (McLachlan and Jaramillo, 1995). A three-zone model was first developed by Erik Dahl: a supralittoral zone characterized by ocypodid crabs in warm regions and talitrid amphipods in

Figure 6 Best models ($p < 0.001$) fitted to the relationships between beach face slope and total (a) abundance and (b) biomass, based on data gathered from 194 sandy beaches on five continents.

temperate areas; a littoral or midshore zone characterized by cirrulanid isopods and spionid and opheliid polychaetes; and a lower shore or sublittoral fringe with many groups, including hippid crabs, mysids, haustoriid and phoxocephalid amphipods, donacid clams, and nephtyid worms. However, the number of recognizable zones depends on beach type. The lower zone tends to reduce or even disappear in very reflective situations, but it can expand to a broad, species-rich terrace under dissipative conditions. The supralittoral zone, above the high-water mark or drift line, is present on all shores. Thus, on most shores there is a clear gradient of increasing species richness as one moves downshore, typically from one or two species in the supralittoral to many species on the lower shore.

Zonation patterns and patchiness respond to an environment spatially and temporally structured by sharp gradients. Aggregations persist in time, but in contrast to sessile species in, e.g., rocky shores, the across-shore position of species, and their population structure vary according to the susceptibility of each species or population component (i.e., recruits and adults) to variations in beach topography. Aperiodic variations related to short-term increases in sea level generated by storm surges and barometric tides will cause the fauna to follow the high-water level; alternatively, seasonal variation occurs when species occupy higher levels during spring and summer than in autumn and winter. As faunal zones are dynamic, temporal studies are needed for a full picture of zonation patterns,

requiring intensive sampling to provide unbiased estimates (Braziero and Defeo, 1996).

Species are mostly concentrated in the lower intertidal zone with richness decreasing upshore. Reflective beaches with coarse sand, dynamic swash action, and rapid drainage may be devoid of intertidal species and harbor only supralittoral forms, whereas loss of species under reflective beach conditions occurs mainly in the lower intertidal, not the supralittoral zone. The Habitat Favorability Hypothesis (Defeo and McLachlan, 2005) postulated that the center of the across- and alongshore range of a species, under optimal conditions of sand moisture, penetrability, and temperature, may be occupied by larger and dominant intraspecific competitors for space or food, whereas small individuals (recruits) may be displaced towards suboptimal conditions on one or both extremes of the distribution range. The same holds true in the case of interspecific competition.

Communities and populations in sandy beaches also vary along a beach (alongshore axis). Species richness within a single beach stretch tends to increase with beach length, decreasing sand particle size and in flatter and wider beaches, as well as from disturbed sites affected by freshwater discharges to undisturbed ones. Gradients in physical factors invoked to explain alongshore patterns have included changing exposure from sheltered to exposed beach ends, changing sand particle size, swash climate, morphodynamics, salinity, a combination of biotic (intra and interspecific interactions) and abiotic factors, and also passive sorting by the swash and active alongshore movements. Variations in human activities along a beach can also be causative factors of alongshore faunal variability (Defeo and McLachlan, 2005).

Microscale

The microscale concerns variations from mm to m and covers interactions in high-density patches and encompasses the area of influence of an individual (Defeo and McLachlan, 2005). Small-scale environmental gradients, together with intra- and interspecific interactions and behavioral factors, may affect community composition at this fine spatial scale on dissipative beaches where densities are much higher than on reflective beaches. Most of the macrofaunal biodiversity is concentrated within the top 20 cm of sediment, adults of large hippid crustaceans and mollusks being the few exceptions to this pattern. The third dimension, vertical distribution in the sand, is an additional way to partition space in order to ameliorate the strength of biological interactions. Investigations about the importance of physical and biological factors on this three-dimensional structure of the sandy beach habitat deserve future research.

Causative Factors: Main Hypotheses

Several models have been proposed to explain patterns in species richness on sandy beaches. Because of the physically controlled nature of beaches and the relative simplicity of the beach environment, these models have focused on explanations revolving around physical rather than biological control. This supports the general applicability of the

Autecological Hypothesis of Noy-Meir as adapted to sandy shores (McLachlan and Brown, 2006), which states that inhabitants of physically controlled environments respond independently to the physical environment. This appears to apply across the range of beach types, but decreasing towards dissipative conditions where biological factors may become more important.

The physical environment impinging directly on beach fauna differs primarily in two main variables: (1) the movement of water over and through the beach face, which has been termed the swash climate, and (2) the sediment particle size range. On most beaches, waves do not break directly in the intertidal but rather in the surf zone. It is only after transformation to bores and crossing the surf zone that wave energy reaches the beach face as swash. Thus, intertidal fauna experience the effects of waves, tides, and the surf zone transformation of these forces as the swash “climate” on the beach face. Sand particle size also changes with beach type, generally being coarser towards reflective states.

There is a consistent relationship between beach type and swash climate features (McArdle and McLachlan, 1991). Dissipative beaches are characterized by swash with extended periods and lengths, variable speeds, most swash activity below the effluent line (water table outcrop), and laminar flow. In general, conditions of fine sediment and long swash periods, with limited swash activity above the effluent line, appear most conducive to developing rich faunas. The key characteristic of this type of swash may, in fact, be its low degree of turbulence and laminar flow over fine, saturated sand, enabling even delicate forms to survive. Reflective beaches display the opposite swash features: the swash climate is extremely harsh; there are high swash speeds throughout the tidal cycle; and waves break directly in the intertidal, resulting in considerable turbulence and increased probability of animals being stranded above the effluent line where unsaturated sand makes burrowing difficult. Swash drainage through the sand is rapid on reflective beaches and there is little inundation time for feeding. Physical stress in the swash zone on the beach face thus increases from dissipative to reflective beaches.

McLachlan *et al.* (1993) refined these ideas to define the Swash Exclusion Hypothesis: the swash climate associated with dissipative beaches is considered sufficiently accommodating and varied to enable most psammophilic macrofauna species to maintain viable populations, but towards reflective conditions harsh swash climate increasingly excludes species. Swash also has important indirect effects on the macrofauna since animals move, feed, and reproduce in the water moving over the beach face. Swash patterns and percolation of water through the beach face above the effluent line are closely coupled.

Swash is not the only factor to be considered: sand also plays a role. Small body sizes tend to be excluded in coarse sediments, and sand particle size influences burrowing rate in a variety of sandy beach species – in most cases coarse sand makes burrowing difficult or impossible. Further, coarse sand can cause vicious abrasion, especially of bivalve shells, and it reduces sand saturation by raising permeability and hastening drainage. Thus, both sediment particle size and swash climate may directly influence the number of species of macrofauna

on wave-exposed sandy beaches. At the population level, the Habitat Harshness Hypothesis postulates that in harsh reflective beach environments, organisms must divert more energy towards maintenance and they therefore have less scope for reproduction, with consequent higher mortality (reviewed in Defeo and McLachlan, 2005).

Bringing all this together, McLachlan and Dorvlo (2005) proposed two levels of control of intertidal sandy beach macrofauna biodiversity: (1) primary control is by tide range and latitude, the former defining the vertical dimension of the intertidal habitat and the latter determining the size of the species pool available to colonize a beach; and (2) secondary control is by harsh swash climates and coarse sand excluding species from colonizing beaches towards the reflective end of the spectrum. According to this hypothesis the primary factors determine the number of species that could occur on dissipative beaches in a particular region, whereas secondary factors limit the number of species that manage to establish populations across the range of beach types by excluding less well adapted species from the harsher conditions on reflective beaches. However, supralittoral species respond differently.

As beach type changes toward reflective conditions, the increasingly inhospitable swash climate and coarse sand exclude more species until, in the fully reflective situation, only supralittoral forms (talitrid amphipods, ocyropodid crabs, insects), which live “outside” the area affected by swash, remain. The Habitat Safety Hypothesis separates intertidal and supralittoral forms, taking into account both swash and sand effects and differences in life histories. This hypothesis suggests that supralittoral species (in contrast to intertidal forms) are safer on reflective beaches, which usually have a distinct berm that is not inundated (Defeo and Gómez, 2005).

Threats

Sandy beaches are subject to many pressures, natural and anthropogenic, and these have recently been reviewed (Defeo *et al.*, 2009). A variety of human activities impact on beaches: recreation, pollution, development, mining, etc. However, the overarching problem is coastal squeeze: beaches are squeezed between rising sea level associated with climate change and increased coastal development associated with expanding human populations and coastal economies. There is considerable inertia in both these seaward and landward forces, so beaches will continue to be threatened for some time, even in the face of actively addressing these issues.

There are great challenges for ecologists studying beaches to design long-term monitoring and experimentation to properly understand the dynamics of key ecological attributes of these systems on different spatial and temporal scales. There are also challenges for coastal managers needing to conserve coastal biodiversity. The ideal management scenario is to have zoning of the shoreline, avoiding strip development and with large areas set aside for conservation. Also essential are generous setback lines that keep development well landward of beaches and dunes and allow space for these systems to retreat naturally in the face of sea level rise. This requires legislation

and enforcement. Sound coastal zone management supported by appropriate legislation and strong enforcement is key.

Discussion and Conclusions

Macrofauna populations and communities in sandy beach ecosystems respond primarily to the abiotic environment. This is a restatement of the idea of a physically controlled community and the Autecological Hypothesis. Thus, composite indices (Dean's parameter, Beach Index, Area) based only on the three physical variables that define a beach (tides, waves, and sand) have high predictive power to estimate the species richness likely to be encountered on ocean beaches. Latitude, beach length, and biological interactions may contribute additionally to explain the remaining variability in the data.

Tropical beaches support more species than do temperate beaches of the same type (McLachlan and Dorvlo, 2005), and long beaches appear to support greater abundance and more species than do short (or pocket) beaches. The former trend may be due to the greater species pool available to colonize beaches in the tropics, whereas the latter trend reflects the more favorable surf circulation patterns on long beaches, which promote greater retention of particulate primary production, better recruitment of planktonic larvae, and larger and therefore more resilient adult populations. Long beaches are also more persistent, that is, unlikely to erode away completely during storms, as can happen on pocket beaches.

Species richness and abundance in sandy beaches increase from microtidal reflective systems through high-energy dissipative systems to ultradissipative tidal flats. Species richness in wave-exposed beaches is therefore predictable on the basis of the physical nature of individual beach environments. Beaches that tend toward the ultra dissipative/tidal flat extreme – the product of large tide ranges, vigorous wave action, and fine sand – harbor most species likely to be encountered in a region. Progressing from this end of the beach continuum towards reflective conditions, that is, decreasing tide range or wave energy or increasing sand particle size, results in beaches becoming steeper and narrower and the increasing exclusion of species. On highly reflective beaches, intertidal macrofauna may be absent and only supralittoral forms remain.

Two physical factors define the immediate environment experienced by the beach macrofauna and may therefore control species richness: the swash climate and sand particle size. Reflective beaches have harsh swash climates in the sense of high turbulence, short swash periods, and rapid swash drainage, resulting in low effluent lines; beaches at the other extreme have more benign swash climates in the form of long-period swash/tidal bores with laminar flow over the beach face and low turbulence, keeping much of the beach saturated because of the slow drainage. All beach fauna can burrow into saturated sand and, in terms of grain size, fine to medium sands seem optimal for most beach fauna. Coarse sand appears to exclude small or delicate forms by crushing and abrasion and most species experience decreasing burrowing efficiency in coarse sands. Thus harsh swash climates and coarse sand appear to exclude many species, the degree of exclusion increasing from the dissipative/macrotidal to the

reflective/microtidal end of the continuum of beach morphodynamic types.

The dynamic, three-dimensional nature of wave-exposed ocean beaches, their shifting populations, and the absence of biological structures (they are even devoid of permanent burrows in most cases) leave limited scope for biological controls of community structure. However, biological interactions (intra- and interspecific) may be more important regulatory agents that previously thought in dissipative beaches, which have higher species richness and densities of organisms and hence greater potential for interactions between individuals (Defeo and McLachlan, 2005).

Beaches are widely valued for their scenic vistas and recreational potential but are threatened by coastal squeeze, being caught between sea level rise on the marine side and expanding development along the shoreline. Strong coastal zone management based on good science is essential to conserve the biodiversity present on sandy beaches.

Several lines of research could improve our understanding of patterns of sandy beach biodiversity and their control. Collaborative work between ecologists and geomorphologists could lead to refinement of our understanding of the coupling between physical and biological process on sandy beaches on various temporal and spatial scales. Key areas for the future will be investigating the importance of physical and biological factors on finer scales, through population studies and experimental work on ecophysiology and behavior. Only by deciphering cause and effect relationships at the individual and population levels we will truly begin to understand the processes that underlie the large scale community patterns that have become clear. Once these processes and mechanisms are better understood, more accurate and useful predictions can be made of global beach diversity patterns and their causes. This capability would be useful in predicting and identifying areas of high diversity and in planning coastal conservation strategies.

Glossary

Bleaching The loss of symbiotic zooxanthellae from corals. Bleaching is usually caused by elevated sea surface temperatures, but it can also be caused by low temperature, sedimentation, extreme salinities or light levels, and bacterial infection.

Cnidaria The marine invertebrate phylum containing the reef-building corals.

Colony A collection of interconnected coral polyps. Often the polyps are connected with living tissue, but sometimes tissue death means that only skeletal material connects them.

Coral Triangle The region, located in the waters of southeast Asia (e.g., Indonesia and Philippines), that contains the highest diversity of corals and other marine organisms.

Hermatypic Reef-building; more recently, this term has been replaced by the term zooxanthellate to refer to coral species with symbiotic algae.

Holobiont The entity that comprises the coral animal and the diverse assemblage of microbes that live associated with the coral.

Planula (plural – planulae) The ciliated planktonic larval stage of a coral.

Polyp The basic unit of the coral animal, consisting of a simple tubular structure with a mouth and ring of tentacles at one end. The polyp sits in a skeletal cup called the corallite.

Scleractinia The taxonomic order of cnidarians that includes the reef-building corals.

Zooxanthellae A diverse group of symbiotic, photosynthetic dinoflagellate algae associated with corals and other tropical marine invertebrates.

Coral Reefs – Rainforests of the Sea

Distribution in Time and Space

Living reefs have a long history, and the earliest reefs were built by microbes (Wood, 1999). However, not all geological eras have consistently had abundant reef growth, and the reasons for the waxing and waning of reefs through time are not entirely clear (Kiessling, 2009). Modern reefs, that is, those built primarily by stony corals in the order Scleractinia (class Anthozoa, phylum Cnidaria), date back at least to the Triassic, and many of the groups found associated with reefs today were established by 50–25 million years ago in the Eocene or Miocene (Bellwood and Wainwright, 2002; Renema *et al.*, 2008).

From a geological perspective, reefs may be defined as masses of carbonate limestone, built up from the seafloor by the accumulation of the skeletal material of many coral reef plants and animals. Reef growth has shaped the face of Earth by creating limestone structures more than 1.2 km thick (Eniwetok Atoll; Szabo *et al.*, 1985) to more than 2500 km long (Great Barrier Reef), although they occupy only approximately 0.6×10^6 km², or approximately 0.1% of the surface of the planet (Reaka-Kudla, 1997). Depending on their proximity to land, coral reefs are classified as fringing reefs (closely paralleling the coastline), barrier reefs (paralleling the coastline farther from shore, with a deep lagoon separating the reef from the shore), or atoll reefs (oceanic ring-like reefs without any relationship to continental or island land masses). Patch reefs are smaller accumulations of coral within lagoons. Darwin (1842) wrote an important early geological

treatise on the formation of reefs; his explanation for the formation of atolls – the legacy of reefs once fringing now sunk volcanoes – was finally confirmed in 1950.

To a certain extent, coral reefs are an enigma: on the one hand, they are among the most luxuriant ecosystems on Earth, supporting high diversity and high biomass, and yet on the other hand, they achieve this status in some of the least fertile waters on Earth. Coral reefs flourish on stable substrates within a relatively narrow range of physical parameters. These requirements include sunlit depths (typically <50 m), normal oceanic salinities, warm sea surface temperatures (generally, average monthly minimum temperatures >18 °C), high oxygen concentrations, and often high water clarity and low nutrient concentrations (Sheppard *et al.*, 2009). Because corals do not tolerate cold temperatures (Lirman *et al.*, 2011; Figure 1), coral reefs are restricted to the tropics, mostly between 30° north and south latitudes. For similar reasons, reefs are best developed and most diverse along the western boundaries of the world's oceans in the tropical western Atlantic (especially the Caribbean) and the Indo-West Pacific, although they can also be found in the tropical eastern Pacific and eastern Atlantic.

Some coral species are more able to tolerate suboptimal extremes, and these form lower diversity reefs where conditions are less favorable. The northernmost genuine coral reefs occur in Japan, the Northwestern Hawaiian Islands, and Bermuda, and the southernmost reefs are found in Australia and South Africa (Spalding *et al.*, 2001; Sheppard *et al.*, 2009). Some reefs of the Persian Gulf tolerate extremes of high temperatures, low temperatures, and high salinities. To a

Figure 1 Distribution of coral genera throughout the Caribbean. The dense packing of generic diversity isopleths along the eastern coast of Florida correlates with the frequency and intensity of cold-water disturbances (e.g., see Lirman *et al.*, 2011).

limited extent, corals are able to adapt to ambient conditions; consequently, the upper lethal temperature for a species in the tropics will be higher than that of the same species in the subtropics.

Biodiversity

Diversity of Major Groups

Coral reefs harbor extraordinary biodiversity in terms of the deep branches of the tree of life, a level of diversity that far exceeds any tropical rainforest. For example, commonly found coral reef animals include the phyla Porifera (sponges), Cnidaria (corals, sea anemones, and their relatives), Ctenophora (comb jellies), Platyhelminthes (flatworms), Nemertina (ribbon worms), Brachiopoda (lamp shells), Mollusca (snails, clams, chitons, and cephalopods), Sipuncula (peanut worms), Arthropoda (crabs, shrimps, and their relatives), Annelida (segmented worms), Echinodermata (seastars, brittlestars, crinoids, sea cucumbers, and sea urchins), and Chordata (sea squirts and fishes). In contrast, the conspicuous and common animal phyla found in tropical rainforests are far fewer, primarily the Arthropoda (insects and their relatives), Mollusca

(land snails and slugs), and Chordata (tetrapod vertebrates). However, these differences between coral reefs and rainforests are paralleled in most comparisons of marine and terrestrial habitats. Life evolved in the sea and only later emerged on land, so most higher taxonomic groups (phyla and classes) are either restricted to or predominantly found in marine environments (May, 1994).

Species Diversity

It is at the level of species (and genus and family) that the diversity of coral reefs stands out from other marine habitats, and just as insects are far more diverse than trees in tropical rainforests, the bulk of the diversity on reefs lies not with the corals but with the many species associated with them. The species diversity of coral reefs greatly exceeds that of any other marine environment on a per-area basis, and probably overall; the only competitor in terms of total diversity is the deep sea, because of its vast extent. On coral reefs, there are also many cryptic species (species that are hard to distinguish morphologically) (Knowlton and Jackson, 1994; Meyer *et al.*, 2005), although whether cryptic species are proportionately more common on reefs than in other marine habitats is less clear.

The epicenter of marine species diversity today occurs in an area known as the Coral Triangle in southeast Asia. The average diversity for locations in the Coral Triangle for many groups is roughly three times that of the most diverse Caribbean locations; for instance, in an assessment of corals, fishes, snails, and lobsters, the Philippines had nearly 1500 species, whereas the western Caribbean had only 450 (Roberts *et al.*, 2002). In some other groups, the differences in diversity are even more extreme; for example, the tropical Indo-west Pacific has approximately 1200 echinoderm species, whereas the tropical western Atlantic has fewer than 150 (Sheppard *et al.*, 2009). However, the center of diversity for coral reefs has not always been located in the current position of the Coral Triangle (Renema *et al.*, 2008), moving across almost half the globe over the past 50 million years.

At present, no fully comprehensive all-taxa biodiversity inventory has ever been conducted on a coral reef, but it is obvious that were this to be done, the total biodiversity would be extremely high. Several efforts have been made to intensively collect from particular locations or habitats for specific groups, and examples of the extraordinary diversity of reefs are listed in Table 1. Bouchet and colleagues have led several such expeditions and found staggering numbers of mollusks and decapod crustaceans. For example, the number of marine mollusk species collected from 42 stations across 295 km² in New Caledonia was 2738 (Bouchet *et al.*, 2002). Results from a more recent effort covering 150 km² in Panglao, Philippines, are roughly 1200 species of decapod crustaceans and 5000–6000 mollusk species (Bouchet *et al.*, 2009). These data depend on collecting, sorting, and identification by many taxonomic experts and are extremely labor intensive. For example, the collections in New Caledonia and the Philippines involved 400 person-days and six person-years, respectively, but that was just the beginning; despite the fact that the Philippines expedition took place in 2004,

six years later, detailed analyses of these collections were still ongoing.

For this reason (and also because of the difficulty of distinguishing cryptic species), efforts to use genetic methods (e.g., barcoding; Hebert *et al.*, 2003) to assess biodiversity have been increasingly employed. For example, Plaisance and colleagues (2009, 2011) using this method found 525 species of crustaceans taken from 6.3 m² of reef rubble and artificial substrates; the number of brachyuran crabs found (168) was equal to approximately 80% of the entire described brachyuran crab diversity of all of Europe. Molecular methods are the only way to census microbial diversity in the ocean, and the numbers are staggeringly large. An early study based on cloning and sequencing of just 14 small samples (each 1 cm²) from corals yielded 430 species of bacteria (Rohwer *et al.*, 2002). More recent analyses using “next-generation” sequencing have made this number seem small (e.g., 300,000 distinct sequences from 10 coral fragments representing bacteria, Archaea, eukaryotic viruses, phage, and fungi (Wegley *et al.*, 2007)).

The numbers presented in the preceding paragraph are absolute counts of what occurred in samples. Statistical methods that examine the prevalence of rare versus common species can be used to estimate the total diversity that would be expected if everything present were counted. Samples from coral reefs typically have many rare species; for example, 20% of the mollusks from the New Caledonia expedition (Bouchet *et al.*, 2002) were represented by a single specimen, as were 38% of the crustaceans analyzed by Plaisance *et al.* (2011) and 23% of the sequences detected by Rohwer *et al.* (2002). The greater the number of rare species, the higher the estimates relative to the observed values; for example, Plaisance and colleagues (2011) estimated that further sampling would have yielded more than 700 crustacean species, and Rohwer and colleagues estimated that further sequencing would have

Table 1 Examples of the extraordinary animal biodiversity of coral reefs

Group	Number of species	Sampling unit	Location	Source
Organisms > 0.2 mm (all groups)	309	Colonies of the coral <i>Oculina arbuscula</i>	Florida	McCloskey (1970)
Infaunal invertebrates	800	10 m ²	Australia	Poore and Wilson (1993)
	350	10 m ²	Aldabra Atoll	Hughes and Gamble (1977)
Polychaetes	158	6 l of sediment	Oahu, HI	Butman and Carlton (1993)
	103	One colony of living coral	Heron Island, Australia	Grassle (1973)
Motile cryptofauna	776	One reef flat	Moorea	Peyrot-Clausade (1983)
Mollusks	2738	295 km ²	New Caledonia	Bouchet <i>et al.</i> (2002)
Crustaceans	525	6.3 m ²	7 sites globally	Plaisance <i>et al.</i> (2011)
Boring cryptofauna	220	Dead coral	Solomon Islands	Gibbs (1971)
Cheilostome bryozoans	46	Hard substrates	Jamaica	Jackson (1984)
Hermatypic corals	362	Milne Bay	Papua New Guinea	Werner and Allen (1998)
	350	Great Barrier Reef	Australia	Veron (1985)
	53	Discovery Bay	Jamaica	Wells (1973)
Fishes (all groups)	1500	Great Barrier Reef	Australia	Sale (1977)
	1039	Milne Bay	Papua New Guinea	Werner and Allen (1998)
	496	Bahamas	Caribbean	Bohlke and Chapin (1968)
	517	Alligator Reef	Florida	Starck (1968)
	23	Single coral head, Big Pine Key	Florida	Bohnsack (1979)

yielded 6000 bacterial sequences. However, when there are many rare species, even these statistical methods tend to underestimate diversity (Coddington *et al.*, 2009).

At present across all coral reefs, there are thought to be approximately 93,000 described species of macroscopic coral reef plants and animals, of which almost 66,000 are invertebrates (Reaka-Kudla, 1997). However, as with tropical rainforests, many coral reef species are undescribed, particularly among the tiniest members of the community, which are the most diverse and least known (Reaka-Kudla, 1997; Table 2). For example, among the mollusks collected in New Caledonia, 52% were smaller than 8.8 mm, and for one family of small parasitic snails, it was estimated that as many as 80% of the species collected may have been undescribed (Bouchet *et al.*, 2002). In addition, many coral reef species are members of the cryptofauna, small organisms hidden in the cracks and crevices of reefs that are far more difficult to census than the large, spectacular corals and fishes that sit on or swim over the reef (Reaka-Kudla, 1997; Richter *et al.*, 2001).

If one cannot rely on the numbers of described species for most groups, how then does one estimate the global diversity of coral reefs? Several approaches have been tried (Bouchet, 2006; Knowlton *et al.*, 2010). Reaka-Kudla (1997) used estimated species–area relationships (number of species = (area)^z), the relative area of coral reefs versus tropical rainforests, and estimated diversity values for rainforests; depending on the figures for rainforest diversity used, she arrived at a low estimate of 618,000 species on coral reefs and a high estimate of 9,477,000 species. Small *et al.* (1998) also used species–area relationships; they counted everything in an aquarium derived from 5 m² of Bahamian coral reef and extrapolated upward to reefs globally, producing an estimate of approximately 2.6–3.2 million species. However, extrapolating from 5 m² to 600,000 km² is problematic, because the exact nature of species–area relationships in the ocean or on reefs is highly uncertain. For example, for the brachyuran crabs censused by Plaisance and colleagues (2011), the estimated number of species ranged from one-third to nearly 600 times the current number of described brachyuran crabs, depending on which end of the range of

common marine estimates for *z* was used. At the other end of the spectrum, Bouchet (2006) estimated that there are 1.4–1.6 million marine species by extrapolating from the well-known brachyuran crab fauna of Europe, and Mora and colleagues (2011) arrived at an estimate of 2.2 million species. Taking the Bouchet (2006) estimate, if coral reefs contained approximately 35% of all marine species (a figure based on the percentage of well-known groups such as fishes that are associated with coral reefs), this would yield an estimate for coral reefs of only approximately 500,000 species (Knowlton *et al.*, 2010). Regardless of which number is closest to the truth, these calculations confirm that with the exception of species in a few showy classes and orders, the vast majority of coral reef species are as yet undescribed. (Mora *et al.* (2011) estimated that for the ocean as a whole, 91% of all species await formal description.) Indeed, most of the DNA sequences obtained from coral reef organisms do not even appear in genetic data banks (Rohwer *et al.*, 2002; Plaisance *et al.*, 2009, 2011).

Factors Responsible for Diversity Patterns

It is far easier to get a clear understanding of patterns of diversity than it is of diversity itself. Typically, well-known groups (especially corals, fishes, and large mollusks for coral reefs) are used as proxies for marine biodiversity as a whole (e.g., Roberts *et al.*, 2002). Although proxies may not accurately reflect detailed diversity patterns for other groups (Mellin *et al.*, 2011), the strongest patterns, such as the concentration of species in the Coral Triangle, are unambiguously robust. Explaining the processes underlying diversity patterns is more of a challenge, however. Explanations for diversity patterns include processes acting at global or regional scales (e.g., area and age), processes acting at local scales (e.g., disturbance from storms, extremes of temperature or salinity, and sedimentation), and patterns explained by null models that require no detailed assumptions about biology.

Biogeographers trying to explain the diversity of the Coral Triangle have long argued over competing (but not mutually exclusive) hypotheses for the region: as a center of origin (a place where species are born), a center of accumulation

Table 2 Estimates of undescribed biodiversity for several tropical marine faunas (Merrell, 1995)^a

Site	Taxon	Number of undescribed species out of the total collected in the taxon	Source ^b
New Guinea	Corals	14 of 362	Werner and Allen, 1998
New Guinea	Fish	3 of 1039	Werner and Allen, 1998
New Guinea	Snails, sea slugs	310 of 564	Gosliner, 1993
Philippines (one island, multiple sites)	Snails, sea slugs	135 of 320	Gosliner, 1993
New Caledonia (295 km ²)	Eulimid snails (parasitic)	Up to 110 of 138	Bouchet <i>et al.</i> , 2002
Hawaii (one island, 6 l of coral reef sediment)	Marine polychaete worms	112 of 158	Dutch, 1988
Great Barrier Reef (two islands)	Marine flatworms (polyclads)	123 of 134	Newman and Cannon, 1994
Gulf of Mexico	Copepods (harpacticoids)	19–27 out of 29	Merrell, 1995

^aThis table has been arranged from larger to smaller body size and suggests that, as with fauna everywhere, especially in the tropics, the smaller the body size, the higher the percentage of undescribed species in the sample.

^bSampling effort and number of samples varied among studies.

(a place where species do not go extinct), or a center of overlap (a place where neighboring faunas, e.g., from the western Pacific and Indian Ocean, come together). An analysis of the ages and ranges of species of fishes and cowries (Bellwood and Meyer, 2009) indicated that the youngest endemics (species confined to a single small location) are not concentrated in the Coral Triangle, making the center of origin hypothesis less likely. Rather, the region seems to be one that accumulates species – but why? An analysis by Bellwood and Hughes (2001) suggests that available shallow water area within 600 km is the strongest predictor of the local species diversity, a finding broadly compatible with predictions from the theory of island biogeography. Interestingly, paleontological analyses of coral reef diversity also point to the importance of peripheral locations in generating new species (Budd and Pandolfi, 2010) and the role of large amounts of suitable habitat in supporting biodiverse communities (Renema *et al.*, 2008). However, there is no relationship between reef diversity and productivity as measured by the accumulation of calcium carbonate, in either modern or fossil reefs (Johnson *et al.*, 2008). It has also been argued that the fact that the Coral Triangle sits midway between Africa and the Americas may contribute its diversity due to geometric constraints (Bellwood *et al.*, 2005), but the shifts in the position of this major biodiversity hotspot through geologic time (Renema *et al.*, 2008) argue against the importance of this kind of purely statistical explanation, as do statistically significant differences between observed diversity patterns and the predictions of null models (Connolly *et al.*, 2003; Dornelas *et al.*, 2006).

These explanations and analyses are regional in scale, and indeed the biodiversity found in any particular location is best predicted by the regional species pool rather than by locally operating factors (Karlson *et al.*, 2004). However, local factors undoubtedly play a role as well, particularly in the context of severe habitat degradation. For example, fish diversity (Jones *et al.*, 2004) and invertebrate diversity (Idjadi and Edmunds, 2006) decline in response to losses in living coral cover or reef three dimensionality. The observed increase and then decrease in coral species diversity with depth (Huston, 1985; Karlson *et al.*, 2004) may reflect both biological factors (a shifting balance of competition and disturbance with depth) and geometric constraints (limiting corals to depths between the sea surface and depths lacking sufficient light).

Interspecific Relationships

With so many species on reefs, it is no surprise that feeding and competitive relationships are extraordinarily complex and diverse. Filter-feeding invertebrates, both on the surface of the reef and lining reef crevices (Richter *et al.*, 2001), capture and retain a high proportion of the material that moves over them, hence the description of a reef as a “wall of mouths” (Hamner *et al.*, 2007). Herbivores, carnivores, and apex predators cruise the reef for food, and deposit feeders sift through the sediments. Less visible but no less important, microbes and multicellular parasites play crucial roles in the foodweb of a healthy coral reef. One analysis of a Caribbean foodweb contained more than 3000 trophic linkages (Bascompte *et al.*, 2005). Competitive relationships are similarly diverse, and

interspecific competition is the rule rather than the exception in competition for space. Studies of competitive relationships on reefs led to the discovery of competitive networks, where instead of a linear dominance hierarchy, relationships have loop structures where A beats B, and B beats C, but C beats A (Buss and Jackson, 1979), a phenomenon in part made possible by the diverse array of chemicals with specialized effects that organisms deploy in self-defense. As in other marine ecosystems, microbes undoubtedly play crucial roles on coral reefs. Modern molecular techniques allow scientists to quantify the expression of metabolic enzymes in order to understand the functional roles that microbes play (Wegley *et al.*, 2007; Dinsdale *et al.*, 2008).

Like tropical rainforests, coral reefs are renowned for the abundance of specialized mutualisms between organisms, relationships where both partners benefit. In addition to the nutritional partnerships between microbes and corals (as well as other groups, to be described in more detail in the following section), there are a host of intricate partnerships linking larger coral reef organisms. Striking mutualisms include the following:

- Coral reef fishes and shrimps that clean parasites from the tissues of fish (Floeter *et al.*, 2007).
- Partnerships between gobies and snapping shrimps, with the partners sharing the duties of watching for predators and digging, respectively (Thacker *et al.*, 2011).
- Cooperation between moray eels and groupers in hunting prey (Bshary *et al.*, 2006).
- Corals that shelter schools of fish and receive nutritional benefits from the fishes’ waste products (Holbrook *et al.*, 2008).
- Crabs and shrimp that live with and defend corals from their predators (Pratchett, 2001).
- Sponge species that grow intertwined and benefit from the complementary characteristics of their partners, such as anti-predator chemicals and resistance to wave damage (Wulff, 1997).

In addition to these relationships with clear benefits to both partners, there are enormous numbers of specialized associations (e.g., shrimp that live only with specific hosts such as crinoids or sea anemones (Bruce, 1977)), where the exact nature of the relationship has never been studied. Some may be mutualistic, others commensal (the host neither suffers nor benefits), and still others parasitic, and sometimes a single relationship can move between these categories (Duris *et al.*, 2011). Whatever the nature of the relationship, the abundance of these partnerships is a clear example of how diversity begets diversity on coral reefs.

Corals as Organisms

Diversity and Evolutionary Relationships

A variety of organisms are referred to as corals. All belong to the phylum Cnidaria, which is characterized by two distinct tissue layers, the inner endoderm and the outer ectoderm, separated by a jelly-like layer called the mesoglea. The basic functional unit of bottom-dwelling cnidarians is the coral polyp,

essentially a cylinder with a central mouth cavity at one end that is surrounded by tentacles armed with stinging cells called nematocysts. All corals that can build reefs secrete a calcium carbonate skeleton, and most contain symbiotic, photosynthetic, single-celled dinoflagellate algae (zooxanthellae) in ectodermal cells that power rapid growth (see Coral-Dwelling Microbes and Coral Nutrition, Growth, Reproduction, and Recruitment). It is this relationship that results in the bathymetric distribution of reef-building corals being largely restricted to high-light environments, because photosynthetically assisted growth makes it possible for new construction to keep pace with physical and biological disturbances (the exceptions being deep-sea corals, some of which can form reefs despite their very slow growth because disturbances are relatively infrequent).

Two classes within the Cnidaria contain major reef-builders. Fire corals are in the class Hydrozoa and can produce a strong burning sensation when touched (hence their name). The other reef-builders belong to the class Anthozoa, which is divided into two groups, the Hexacorallia and the Octocorallia. Among the octocorals, there are two species that are reef-builders – the blue coral and the organ-pipe coral. True corals belong to the order Scleractinia within the hexacorals. Several other cnidarians are conspicuous on reefs but are not reef-builders: the stylasterine corals (hydrozoans, which build skeletons but lack zooxanthellae), the soft corals and gorgonians (octocorals, which are important space occupiers but lack stony skeletons), and the sea anemones, corallimorphs, and black corals (all hexacorals, which live on reefs but lack stony skeletons). The rest of this section will focus primarily on scleractinians, as they are the most important of all the reef builders.

The understanding of scleractinian evolutionary relationships has been radically altered, thanks to the application of molecular methods. For example, a recent analysis showed that 11 of 16 families were incorrectly defined and an entire family of corals endemic to the Atlantic had been overlooked (Fukami *et al.*, 2008). Scleractinians with zooxanthellae are sometimes referred to as hermatypic (reef-building) corals, but ahermatypic (non-reef-building or azooxanthellate) corals are comparably diverse (669 and 656 species, respectively; Cairns, 1999) and are scattered across the scleractinian tree of evolutionary relationships (Kitahara *et al.*, 2010). Some scleractinian families are exclusively azooxanthellate, others exclusively zooxanthellate, and a few contain a mixture of zooxanthellate and azooxanthellate species (including a few species that facultatively contain zooxanthellae).

Coral-Dwelling Microbes

Corals cannot be simply understood as animals. Rather, they contain a complex assemblage of microbes, and for that reason the term “coral holobiont” has come into increasing use to refer to this animal-microbial entity (Rosenberg *et al.*, 2007; Bourne *et al.*, 2009). As noted (see Species Diversity), a single coral contains a diverse assemblage of endolithic algae, bacteria, Archaea, fungi, and viruses (Wegley *et al.*, 2007). Some are pathogens and others are beneficial, but the roles of most of these microbes are unknown.

The best understood of the microbial associates of corals are the zooxanthellae, because of their importance for coral nutrition. The understanding of the diversity and relationships among the zooxanthellae has also been revolutionized by molecular methods. What was once thought to be a single dinoflagellate species, *Symbiodinium microadriaticum*, is now recognized as a complex assemblage of distantly related groups (types A–F), each of which contains considerable genetic diversity (Baker, 2003). Different species of zooxanthellae, most of which remain identified only by numbers and associated genetic profiles, have different preferences with respect to host, light, temperature, and other environmental characteristics. Importantly, they also have different life histories (e.g., speed of colonization into coral tissues) and different sensitivities to stress, and provide different benefits to their hosts (Lajeunesse *et al.*, 2009; Jones and Berkelmans, 2010).

Coral Nutrition, Growth, Reproduction, and Recruitment

Reef-building corals depend on their zooxanthellae for nutrition via the transfer of photosynthetically fixed carbon, and eventually starve to death and die without them. Although the role of zooxanthellae in this autotrophic nutrition of corals was long emphasized, it is increasingly recognized that shallow-water, reef-building corals also have a diverse array of other nutritional options (Houlbrèque and Ferrier-Pagès, 2009). Heterotrophically they are able to capture food (detritus, bacteria, ciliates, and zooplankton) with their tentacles and mucus nets, as well as absorb dissolved nutrients directly. Heterotrophy accounts for anywhere from 0% to 66% of the fixed carbon that goes into skeleton formation and contributes from 15% to 35% of the metabolic needs of healthy corals. Feeding by corals increases tissue growth and skeleton formation, and benefits the zooxanthellae as well. The importance of heterotrophy varies as a function of the coral species and environmental conditions.

A few coral species typically exist as solitary polyps (e.g., the mushroom corals) that grow by increasing the size of the polyp. Most coral species, however, are colonial, consisting of tens or hundreds to many thousands of polyps. These corals grow by asexually budding new polyps and by extending the height of the skeletal cups (the corallites) in which the polyps sit. The shape of the resulting skeleton is species specific at the corallite level, but the overall shape of the colony is also influenced, within limits, by environmental conditions (Todd, 2008). Although corals grow relatively slowly in general (often less than 1 cm yr⁻¹), under optimal conditions, the growth rates of branching corals in the genus *Acropora* can exceed 10 cm yr⁻¹ (Lirman *et al.*, 2010). In many cases, the polyps of the colonies are interconnected with living tissue, but in some types of growth, the polyps become disconnected because of the death of connecting tissues, even though the skeletal structure connecting the corallites remains intact. In addition, partial mortality (e.g., caused by predators) can break the physiological connection between polyps.

Some species of corals regularly form new colonies – entities that are physically and physiologically separate – through

asexual reproduction. Typically this happens through fragmentation, but asexual production of larvae and even the budding off of polyps without skeletons also occur (Yeoh and Dai, 2010). This form of reproduction can result in concentrations of apparently separate colonies that are genetically identical; the only unambiguous way to determine if this form of asexual propagation has occurred is through genetic methods. The complexity of these processes (asexual reproduction as well as partial mortality) means that it is nearly impossible to tell the age of a coral from its size (Hughes and Jackson, 1985). Also, size rather than age is a better predictor of important life history characteristics, such as when sexual reproduction occurs.

Sexual reproduction takes place in a variety of ways (Baird *et al.*, 2009). Depending on the species, a given colony may be hermaphroditic, producing both eggs and sperm, or gonochoric, producing either eggs or sperm. Fertilization typically occurs in one of two ways: through spawning, in which gametes (eggs and sperm) are released simultaneously into the water column, where fertilization takes place, or by brooding, in which sperm are released into the water column and are taken inside the maternal coral polyp to fertilize the eggs stored there. Hermaphroditic broadcast spawning is the most common mode of reproduction, and most genera exhibit only one reproductive mode. Broadcasting species tend to reproduce once a year, and the eggs and larvae typically lack zooxanthellae; not only do members of one species reproduce in synchrony, but also often multiple species do so, a phenomenon termed “mass spawning.” For example, on the Great Barrier Reef, up to 30 species on a single reef may spawn within a few hours of each other. Brooders, however, often reproduce over multiple months in accordance with a lunar cycle, and their larvae often have zooxanthellae. Most broadcasting corals must cross-fertilize, but some brooding species are capable of self-fertilization.

Coral larvae (called planulae) can often settle within a few days of fertilization or release from the brooding colony, but in many species, they are capable of surviving much longer (more than 200 days in the laboratory in some cases) (Graham *et al.*, 2008). It is not easy to estimate the dispersal distances of coral larvae, but many probably settle relatively close to their parents (on the same reef or nearby reefs within a few kilometers). In addition, the dispersal of the larvae of brooders is often more limited, so that inbreeding as well as selfing may occur (e.g., Sherman, 2008), although the presence of zooxanthellae in the larvae may also facilitate occasional long-distance dispersal. Planulae prefer to settle on hard, relatively well grazed surfaces (often coralline algae) (Arnold *et al.*, 2010), after which they metamorphose into a cemented polyp.

The Disappearance of Living Corals and Coral Reefs

Reefs and People

Reefs are subject to influences that come from the land, the air, and the sea, many of them directly related to human activities (Figure 2). Approximately 10% of the human population lives within 100 km of coral reefs, and 91% of these people are citizens of developing countries (Donner and Potère, 2007), where environmental regulations are often lacking or poorly enforced. Coastal cities and coast-based tourism (which can dwarf local populations in terms of numbers of people and resource demands) have been growing rapidly. This results in increasing demands for potable fresh water, food and other renewable resources (including seafood and marine curios), power, and cleared land. Globally, demand for all Earth's resources has inexorably increased due to increases in both human population numbers and increasing consumption per capita.

Figure 2 Coral reefs are subject to terrestrial, atmospheric, and oceanic influences. Sediments, nutrients, and toxins, released from activities such as deforestation, agriculture, and industry, are hydrologically transported to coral reefs through local rivers. CO₂ buildup in the atmosphere increases CO₂ concentrations in the ocean and alters climate patterns. Finally, diseases are circulated by ocean currents. Reefs located near human population centers are subjected to multiple stresses simultaneously and so suffer losses in diversity and cover. Adapted with permission from Wilkinson CR and Buddemeier RW (1994) *Global Climate Change and Coral Reefs: Implications for People and Reefs*. Report of the UNEP–IOC–ASPEI–IUCN Global Task Team on the Implications of Climate Change on Coral Reefs. Gland, Switzerland: IUCN.

Meeting local demands can have multiple negative effects on the local environment. Water quality degrades as strains are placed on whatever water treatment systems exist. Poorly executed construction projects and deforestation result in erosion, and the promise of jobs often leads to dredging of ports and filling in of coral reefs for airports and resorts. Meeting food needs leads to increasing fishing, as well as intensified agriculture and aquaculture. The latter two reduce pressure on wild stocks, but can result in elevated nutrients in coastal waters, the introduction of nonnative species, and contamination by pesticides and other toxic materials. Water temperatures and salinities can be locally impacted by power and desalination plants and water diversion projects.

Local populations (permanent or transient) are not the only source of stress on coral reefs. Most notably, increasing greenhouse gas emissions are causing the ocean to be both warmer (Figure 3) and more acidic (see Greenhouse Gas Emissions). This is already creating conditions unlike those of the past 420,000 years, and projections show a drastically altered ocean by the end of the century (Hoegh-Guldberg *et al.*, 2007). Global demand by people far from reefs for coral reef products also contributes to both overharvesting and destructive harvesting methods, especially the use of dynamite and cyanide to support the live fish food trade (McManus *et al.*, 1997).

Extent and Patterns of Loss of Corals and Coral Reefs

As a consequence of increasing human impacts summarized above and described in more detail later, coral reefs around the world have been declining at an alarming rate. This trend was first starkly outlined for the Caribbean, where the cover of living coral declined by approximately 80%, from approximately 50 to 10% coral cover, between 1997 and 2001

(Gardner *et al.*, 2003). Although the Pacific remains in better condition, it is on the same trajectory, with the average amount of living coral dropping approximately 1% per year since the mid-1980s (Bruno and Selig, 2007). These recent declines came on top of earlier losses, which began centuries ago in some locations (Pandolfi *et al.*, 2003). In 2008, one-third of all coral species were deemed to be at risk of extinction (Carpenter *et al.*, 2008). Because dead coral skeletons are subject to bioerosion, eventually the loss of living coral results in the loss of three-dimensional structure and even reef rock itself (Lewis, 1992; Sheppard *et al.*, 2005; Alvarez-Filip *et al.*, 2009).

Sometimes, the loss of living coral at any one site is rapid, exhibiting the dynamics of thresholds and tipping points. For example, much of the collapse of coral reef ecosystems on the north coast of Jamaica occurred within a decade (Hughes, 1994); chronic and severe overfishing underpinned the collapse of the reefs following the loss of the remaining dominant grazer, the long-spined sea urchin, *Diadema antillarum*, due to disease. Thresholds are often associated with the establishment of alternate stable states, for example, the replacement of corals by macroalgae or other space occupiers, which inhibit the recovery of the corals (Hughes *et al.*, 2010).

Major Agents of Coral Mortality

Corallivore Explosions

Fishes and a variety of invertebrates feed on corals, and a few of these corallivore species can have dramatic impacts on reefs (Rotjan and Lewis, 2008). Indeed, the first scientific awareness of threats to coral reefs came with outbreaks of the crown-of-thorns seastar, *Acanthaster planci*, in the 1960s. Individuals numbering in the hundreds of thousands were observed to

Figure 3 A model of sea surface temperatures based on greenhouse gas concentrations and El Niño Southern Oscillation events predicts temperatures will exceed normal thresholds for many reefs in the very near future. The horizontal lines indicate the temperature thresholds at which corals begin to bleach (see Coral Bleaching). Reproduced from Hoegh-Guldberg O (1999) Climate change, coral bleaching and the future of the world's coral reefs. *Marine and Freshwater Research* 50: 839–866, with permission from CSIRO.

reduce drastically the amount of living coral cover on affected reefs. Although there was initially debate as to whether this was a natural phenomenon, scientists gradually realized that frequent massive outbreaks could not have occurred in the past, because otherwise the coral communities would have been far different than observed before the outbreaks. Controversy over the relative importance of removal of predators on crown-of-thorns versus nutrients in the water favoring survival of their larvae has persisted for decades, and there is evidence for both hypotheses. Recent work suggests that primary outbreaks are associated with flood waters, pointing to a crucial role for nutrients (Fabricius *et al.*, 2010), but marine protected areas with healthy populations of potential predators on crown-of-thorns also have reduced outbreaks (McCook *et al.*, 2010). Although crown-of-thorns have received the most attention, other coral feeders can have significant effects on coral numbers, and some, like the snail *Drupella*, can also have population outbreaks that cause extensive coral loss.

Algal Overgrowth

When corals die from other causes, their bare skeletons are rapidly overgrown by other organisms, often macroalgae. Algae are potentially capable of overgrowing living corals because they grow much faster than corals do. Algae also have direct, negative effects on adjacent corals because of compounds that they release. Some macroalgae release allelochemicals that directly kill corals (Rasher *et al.*, 2011). Algae also release dissolved organic carbon that can fuel the growth of bacteria, which in turn kill coral (Smith *et al.*, 2006).

Both excessive nutrients in the water (eutrophication) and overfishing (particularly the fishing of herbivores) can shift the competitive balance between these two space occupiers and favor algae over corals. The relationships linking overfishing with algal overgrowth are not always clear, however. For example, a simple prediction in this context might be that increased numbers of apex predators might reduce the number of herbivorous fish, and consequently result in more macroalgae on reefs, an example of a trophic cascade. Yet the presence of apex predators does not necessarily result in a decrease in herbivorous fish and a blooming of algae (Mumby *et al.*, 2006; Sandin *et al.*, 2008).

Coral Bleaching

If the relationship between the coral and its symbiotic zooxanthellae is disturbed, bleaching occurs. The term “bleaching” describes the condition in which the zooxanthellae die, exit, or are expelled from the coral, thus showing the stark white skeleton beneath the coral tissue (Figure 4). Without the symbiotic algae, corals lose their vital source of nutrition, slow their growth rates, stop reproducing, and sometimes die (Van Oppen and Lough, 2009). When environmental conditions return to normal, zooxanthellae repopulate the coral. Susceptibility to bleaching is influenced by the species of coral in question, the species of zooxanthellae it hosts, and the environmental history of the coral holobiont. It can be caused by a variety of stressors, including excessive heat or cold, low

Figure 4 In 1997 and 1998, severe coral bleaching episodes were caused by dramatically elevated sea surface temperatures worldwide. A vast majority of elkhorn corals (*Acropora palmata*) on Looe Key, in the Florida Keys, bleached stark white (photograph by James W. Porter).

salinity, and excessive light or dark. Of these, warming oceans pose the greatest threat.

Reef-building corals typically live much closer to their upper lethal temperature (the temperature that will kill or disable them) than to their lower lethal temperature. A rise in the water temperature of only 1 °C above the normal summertime average is much more stressful physiologically than a drop of 1 °C below this value. This sensitivity to even small increases in temperature is due to the effect of elevated temperature on the photosynthesis of zooxanthellae. Temperature-induced bleaching occurs in one of two ways, either by brief exposure to moderately increased temperature or by prolonged exposure to slightly elevated temperature. Degree heating weeks (DHWs) are often used to characterize accumulated thermal stress over 12-week intervals; for example, two DHWs are equivalent to 2 weeks at 1 °C above the expected summer maximum temperature or one week at 2 °C above the expected maximum. Widespread bleaching and some mortality occurs when DHW reaches 8 °C weeks.

Over the past 20 years, there has been a dramatic increase in the number of reef provinces bleaching (Figure 5) and in the severity of these bleaching episodes. During the 1982–3 bleaching event, Glynn and Feingold (1992) documented up to 95% loss of corals in the Galapagos Islands. Mass mortalities have since also been reported for Australia and the Indian Ocean (Hoegh-Guldberg, 1999) and the Caribbean (Eakin *et al.*, 2010).

Disease

Coral reefs are no exception to the truism that, even in healthy ecosystems, disease is part of the natural environment. Diseases in the ocean, however, are poorly understood, and most coral reef pathogens are unknown. For instance, in a recent review, 18 coral diseases were listed as recognizable by their symptoms, but only six pathogens were identified, the first just in 1996 (Bourne *et al.*, 2009). Stony corals are not the only

reef organisms that are affected by disease. In 1982 and 1983, almost all of the black spined sea urchins, *Diadema antillarum*, in the Caribbean died from an unknown pathogen (Lessios *et al.*, 1984), which triggered the replacement of corals by seaweeds in many locations, as noted above. Sponges have

Figure 5 Recently, the frequency, intensity, and geographical extent of bleaching episodes have increased. During the strongest bleaching event to date, 1998, bleached corals were recorded for the first time in many provinces. Reproduced from Hoegh-Guldberg O (1999) Climate change, coral bleaching and the future of the world's coral reefs. *Marine and Freshwater Research* 50: 839–866, with permission from CSIRO.

also suffered from diseases, and these diseases are even less well understood (Wulff, 2007).

Although the specific agents responsible may be unclear, the ecological consequences are not. The Caribbean has been particularly hard hit, where two of the most important reef-builders, *Acropora palmata* and *A. cervicornis*, have recently been put on the US endangered species list because of catastrophic losses. Because corals grow slowly and live for decades or centuries, diseases have far-reaching impacts on coral reefs, both today and on geological time scales (Aronson and Precht, 1997). Although the lack of baseline data makes it difficult to measure with precision, it seems clear that the incidence of diseases on coral reefs has increased (Coral Disease Working Group, 2007). Paleontological evidence has demonstrated that disease outbreaks in Belize have no historical precedent over the past 5000 years (Aronson and Precht, 1997), lending credence to the idea that disease outbreaks on the present scale are a recent phenomenon.

The reasons for increasing amounts of disease on coral reefs remain debated. Traditionally, diseases have been viewed as the outcome of infection by specialized pathogens, but coral reef scientists have increasingly turned to the hypothesis that environmental stress may be weakening immune systems or causing normally relatively benign microbes to grow out of control (Figure 6; Coral Disease Working Group, 2007). Support for this comes from observations correlating water quality with disease severity and outbreaks of disease

Figure 6 Coral disease-stress model. Although natural background levels of disease are expected even in healthy ecosystems, a variety of stresses could lead to the suppression of the disease defense systems in coral. The consequence of reduced health would be an increase in the number of pathogenic organisms, susceptible species, outbreak locations, and mortality rates.

Figure 7 The potential interaction between coral bleaching and disease can be seen in this montage of images from 1997 to 1998. Healthy colonies of *Montastraea annularis* (left (May, 1997)) on Looe Key, in the Florida Keys, bleached in late summer due to elevated sea surface temperatures (middle (October, 1997)). This colony also contracted black band disease (middle, lower part of the image). By May 1998 (right), most of the colony had recovered, but the black band damaged tissue did not.

following bleaching events (Figure 7; Miller *et al.*, 2009). Some diseases are caused by normally terrestrial pathogens; the fungus *Aspergillus sydowii* is associated with sea fan disease and is normally found in soil, and the bacterium *Serratia marcescens* attacks elkhorn corals and is found in wastewater (Sutherland *et al.*, 2011).

Underlying Anthropogenic Causes of Coral Mortality and Reef Loss

Direct Destruction

Just as tropical rainforests are threatened by the clearing of land, direct destruction of coral reefs also occurs, although unlike the situation for forests, this is not the most important cause of reef loss globally. Nevertheless, in some locations, direct destruction of coral reefs is a major threat. For example, in southeast Asia, destructive fishing methods associated with the live fish food trade, in particular the use of dynamite or cyanide, have caused extensive reef loss (McManus *et al.*, 1997). Recovery is often lengthy, especially after dynamiting, which produces a highly unstable substratum of small coral

fragments. Dredging to expand ports and even the harvesting of corals for building material can locally inflict substantial losses.

Some corals are also collected for the aquarium trade or as curios. All corals have been listed under Appendix II of the Convention on International Trade of Endangered Species (CITES) since 1990. This listing stipulates the regulation of international trade in corals but does not prohibit it, and considerable trade in corals continues (Green and Hendry, 1999).

Poor Water Quality

Because reefs thrive in clear, clean seawater, human activities that lower water quality can cause coral mortality and loss of reefs. Terrestrial runoff associated with deforestation or coastal construction delivers sediments, inorganic nutrients, organic matter, and potential pathogens onto reefs. These can have direct negative effects on the corals (e.g., smothering from sediments and lowered light availability) or indirect effects (e.g., favoring coral predators, competitors, pathogens, or bioeroders) (Fabricius, 2005). Terrestrial runoff associated with agriculture, mining, and manufacturing may also carry heavy metals and pesticides onto reefs, which directly

compromise coral health (Howard and Brown, 1984; Guzmán and Jiménez, 1992). Extreme salinities associated with freshwater diversion and powerplant operations can also locally affect corals. Of these, the most important are the impacts of sediments, nutrients, and organic matter, which threaten 22% of reefs globally (Fabricius, 2005).

Sedimentation influences coral communities through lethal and sublethal mechanisms. Although increased sedimentation causes direct mortality of corals by smothering them, most effects are sublethal. Corals remove sediments by secreting copious amounts of mucous that trap the sediments, and this constitutes a substantial energy drain. Despite this removal process, sediments tend to accumulate in depressions on large, massive colonies and cause death to those patches. Suspended sediments in the water also decrease the amount of light available for photosynthesis, resulting in lower rates of growth and reproduction, and a reduction in the maximum depth at which corals can grow. In addition, coral larvae are not able to settle on loose sediments, and sedimentation negatively affects the crustose coralline algae on which many coral larvae prefer to settle. Consequently, if a fine layer of sediments covers the reef benthos, successful recruitment drops dramatically.

Inorganic nutrients and organic matter primarily affect corals via their impact on other organisms that interact with corals. When nutrients are low, corals are able to outcompete other space occupiers, such as photosynthetic seaweeds and filter feeding sponges and tunicates, because tight nutrient cycling between the coral host and zooxanthellae affords a competitive advantage to the coral. When nutrients are added to the system, the competitive edge shifts to faster growing macroalgae and filter feeders. Coral recruitment is also reduced because algae can prevent coral larvae from settling. The growth of boring organisms is promoted, which weakens the reef structure itself and increases the probability of storm damage. Some coral diseases also are more virulent when the water has high levels of inorganic nutrients, and excess organic carbon can be even more detrimental than inorganic nutrients because it fuels the growth of bacteria (Kline *et al.*, 2006). Coral predators may also increase in number because terrestrial runoff stimulates the growth of phytoplankton on which their larvae feed; the best evidence of this comes from studies of outbreaks by the voracious coral predator *A. planci*, the crown-of-thorns seastar (Fabricius *et al.*, 2010). Finally, increased phytoplankton reduces water clarity and results in a concomitant decrease in light availability for photosynthesis by zooxanthellae.

Overfishing

Reduction in fish density and biomass is typically one of the first consequences of human activities (Jackson *et al.*, 2001). The effects of fishing (which also includes harvesting of invertebrates) stem from the destruction of the reef itself because of the methods used (reviewed earlier), but even more importantly, from the indirect consequences of the removal of fishes from the community. These latter effects on reef communities have been so pervasive that only recently have reef scientists recognized that most of the reefs they had been studying were far from pristine (Jackson, 1997). Expeditions

to the remote reefs of the central Pacific have shown that the fish communities of unfished reefs typically are dominated by apex predators, which represent 50% or more of the biomass in these areas (Friedlander and DeMartini, 2002; Sandin *et al.*, 2008). The effects of fish removal can be pervasive across the reef community. A comparison across a gradient of human disturbance in the Northern Line Islands showed that with increasing human densities, apex predators disappeared, percentage cover of corals and coralline algae declined, and microbes (including potential pathogens) increased in density in the seawater (Sandin *et al.*, 2008; Dinsdale *et al.*, 2008).

Loss of herbivores is especially detrimental to reefs, because, as with increasing nutrients, it results in a shift in the competitive balance in favor of algae at the expense of corals. In most locations, the effects of overfishing on coral–algal competitive relationships is much greater than the effects of elevated nutrients. The effects of overfishing can be complex, as herbivores differ in terms of their impact on algal communities (e.g., Burkepile and Hay, 2008), and sometimes the impacts of herbivores have not been anticipated. For example, after a caging experiment that resulted in extensive algal growth was ended, the algae were largely consumed by batfish, a previously largely unstudied member of the fish community (Bellwood *et al.*, 2006). Other fishes also play important and sometimes complex roles. For example, removal of certain predators can contribute to outbreaks of corallivores, such as crown-of-thorns starfish.

Invasive Species

Humans routinely move organisms from place to place, either intentionally (for aquaculture or aquaria) or unintentionally (e.g., in ballast water). Most fail to prosper in their new locations, and invasive species until recently have been largely ignored as a threat to coral reefs. This has changed, however, particularly with the explosive proliferation of lionfish, native to the Indo-Pacific, throughout the Caribbean. A single lionfish on a patch reef can consume nearly 80% of the arriving fish recruits in 5 weeks (Albins and Hixon, 2008), so that their huge numbers greatly exacerbate the effects of overfishing in the region, which may itself have contributed to the initial spread of the invaders. Trophic cascades involving the invasion of lionfish, the loss of herbivores that they prey on, followed by the expansion of algae have already been documented on deep reefs, which were previously less affected by other local anthropogenic stressors (Lesser and Slattery, 2011). Other invasive species, for example, seaweeds introduced in the context of aquaculture, have also caused problems on reefs (Conklin and Smith, 2005).

Greenhouse Gas Emissions

Greenhouse gas emissions have two primary effects, rising temperatures and falling pH, and the consequences of both of these for coral reefs are dire (Hoegh-Guldberg *et al.*, 2007). The most conspicuous consequences of increased CO₂ concentrations to date have been the increase in coral bleaching and coral disease associated with rising temperatures, both discussed earlier. However, coral reefs are also affected in other

ways by rising temperatures and will increasingly be affected by more acidic ocean water.

Rising temperatures have two important effects on coral reefs in addition to their direct effects on coral physiology. First, the intensity of major storms, such as hurricanes, is expected to increase with increasing temperatures. These storms cause direct physical destruction of corals by increased wave action and scouring. Many coral reefs lie squarely within the two belts flanking the equator that are characterized by frequent and intense tropical storms, and healthy coral reefs recover relatively quickly from these disturbances. However, reefs that are impacted by other stressors lack resilience, and a major storm can set the stage for continued declines (Hughes, 1994). Second, and similarly, healthy coral reefs can usually keep up with rising sea levels associated with rising temperatures through the upward growth of coral colonies, but compromised reefs may “drown.”

The detrimental effect of lower pH on the ability of corals to secrete their skeletons is now an area of active research, although the threat posed by ocean acidification was recognized only relatively recently (Kleypas *et al.*, 1999). Skeletal secretion by newly settled larvae can be strongly disrupted (Cohen *et al.*, 2009), and in some species, an entire colony can lose its skeleton altogether (Fine and Tchernov, 2007). Over the next century, grossly elevated atmospheric CO₂ concentrations are expected to reduce the ability of corals to calcify; Kleypas *et al.* (1999) argue convincingly that this has already begun (Figure 8).

Environments today that naturally have low pH and the response of fossil reefs to past environmental change give a window into what reefs may look like in the future. Studies of reefs with CO₂ seeps in Papua New Guinea exhibiting values of pH ranging from 8.3 to less than 7.7 suggest that CO₂ concentrations of 750 parts per million (ppm; 750 ppm is the level predicted for the end of the century under many business-as-usual scenarios) will cause declines in coral diversity, coral recruitment, and the abundance of structurally complex coral species (Fabricius *et al.*, 2011). For pH values less than 7.7 (equivalent to CO₂ concentrations of more than 1000 ppm), there was no coral reef growth. The fossil record also provides cause for extreme concern, as the four most recent reef crises, including two of the five mass extinctions since the evolution of complex life, occurred during periods of ocean acidification combined with rapid global warming (Pandolfi *et al.*, 2011).

Consequences of Loss of Corals and Coral Reefs

Species Loss

Both the International Union for Conservation of Nature and Natural Resources (IUCN) and CITES define extinction as occurring when a species is not definitely located in the wild during the past 50 years. With this strict definition, and in the complete absence of monitoring efforts at the appropriate temporal and spatial scales, extinctions in the marine environment in general and on coral reefs in particular are almost impossible to prove. An example of this kind of difficulty can be seen in the announcement of the extinction of an eastern Pacific coral species due to severe El Niño conditions,

Figure 8 Projected changes in reef calcification rates are depicted as a percentage of conditions from 1880. This model suggests that oceanic conditions in the year 2100 will be substantially less optimal for coral growth than in the nineteenth century. Reprinted from Kleypas JA, Buddemeier RW, Archer D, Gattuso J-P, Langdon C, and Opdyke BN (1999) Geochemical consequences of increased atmospheric carbon dioxide on coral reefs. *Science* 284: 118–120, with permission from American Association for the Advancement of Science.

and an almost immediate retraction when it was subsequently rediscovered alive (Glynn and Feingold, 1992). Carlton (1993), in his review of modern marine invertebrate extinctions, included only one tropical species in his list, the Indo-Pacific mangrove periwinkle, *Littoraria flammea*, which was last seen in the mid-1800s. It has been argued that marine species might generally be less vulnerable to extinction than terrestrial species.

However, it seems likely that some coral reef species have gone extinct without being noticed. Reaka-Kudla (1997) points out that most species on coral reefs are small and that

these smaller species also have much smaller geographic ranges, making them more prone to extinction if their habitats are destroyed. For example, some species of coral reef fish have been observed only in a single bay. In addition, the widespread destruction of coral reef habitat makes future extinctions (an extinction debt; *Tilman et al., 1994*) more likely because of the correlation between the area of suitable habitat available and the number of species that can be sustained. In general, damaged reefs support fewer species of fishes and invertebrates than do healthy reefs (*Jones et al., 2004*; *Idjadi and Edmunds, 2006*), although coral associates are probably less at risk of global extinction than corals themselves (e.g., *Graham et al., 2011*).

Because of their vulnerability to so many different aspects of human activities, corals are of particular concern when it comes to extinction. For species that must cross-fertilize, scarcity of potential mates may hamper reproductive success. Indeed, a recent analysis (*Carpenter et al., 2008*) suggested that as many as one-third of all coral species may be at risk of extinction due to the combined effects of global change and local stresses.

Loss of Ecosystem Goods and Services

Humans benefit from the resources, physical protection, and recreational opportunities that coral reefs provide (*Hoegh-Guldberg, 1999*). In one study, the total global value was estimated at nearly US\$30 billion annually (*Conservation International, 2008*). Tourism, coastal protection, and biodiversity (all nonextractive sources of value) constituted more than 80% of the total.

Corals are valuable just as physical structures. They are used for building materials in areas where there is no viable alternative. More importantly, coral reefs reduce coastal erosion by protecting coastlines from severe storms (*Sheppard et al., 2005*). This is particularly important in tropical waters where hurricanes and tropical storms occur frequently.

Coral reefs are crucially important for local economies. The reefs support valuable fisheries for local consumption and for the aquarium trade. Throughout the Caribbean and Indo-Pacific, local diets derive nearly 60% of their intake of protein from these reefs. The life cycles of many commercially important fish and shellfish are dependent on the presence of healthy mangrove swamps, coral reefs, seagrass beds, and coastal lagoons. A multibillion dollar tourism industry is supported by tropical coral reefs and is a critical source of income, particularly for small island nations with few alternative resources to exploit. Even in developed countries, the financial benefits of healthy reefs are substantial; the Great Barrier Reef is estimated to bring AUD5.5 billion and more than 53,000 jobs to the Australian economy (*McCook et al., 2010*).

Finally, pharmaceutical companies have discovered naturally occurring bioactive compounds among the organisms found on coral reefs: antitumor compounds have been found in the mucus of corals, anti-inflammatory agents have been isolated from soft corals, and coral has successfully been used as a bone substitute in reconstructive surgeries. Cone snails represent a classic example; their toxins have many potential and actual

uses (e.g., the pain reliever Prialt derived from the toxin of *Conus magus*), but most to date remain unexplored. Many cone snails are found on or near coral reefs and are themselves highly threatened; more than 20% of cone snails have ranges of less than 3500 km², and people threaten 50% or more of the ranges of 69% of cone snail species (*Chivian et al., 2003*).

Coral Reef Conservation

Local Management and Restoration

Traditionally, conservation has operated through the principle of protecting individual species from extinction. On reefs, this approach has been applied to a limited number of commercially harvested species, notably sharks and species considered at risk from the aquarium trade such as seahorses. In the case of the former, outright bans have been implemented; for example, shark finning is now illegal in Palau and the Bahamas. The rationale is strictly economic – these species are worth more as sights to be seen than fins to be consumed. A number of threatened aquarium fishes are increasingly captive bred because of concerns about overharvesting; examples include anemone fishes, cardinal fishes, and seahorses, as well as some corals.

Increasingly, however, conservation has turned to the protection of entire ecosystems (so-called ecosystem-based management), a trend that is particularly welcome for coral reefs given the impossibility of protecting huge numbers of species one by one. For coral reefs, this involves reducing local stressors to increase the resilience of reefs, so that they can recover from disturbances whose global causes (e.g., warming temperatures) cannot be locally managed directly (*Hughes et al., 2010*).

The two primary local stressors that require tackling are poor water quality and overfishing. Marine protected areas are the primary way that overfishing has been addressed, in part because tropical fisheries are so diverse that management of individual species is not practical. Sometimes this involves modification of fisheries practices – for example, bans on fishing parrot fishes, not because parrot fishes are themselves endangered in most cases (the highly prized bumphead parrot fish being an exception in this regard), but because they play a crucial role in keeping seaweeds under control. In developed countries, no-take marine protected areas have been especially highlighted. The Great Barrier Reef is the gold standard in this regard, with approximately 30% of the reef in no-take status. However, most coral reefs lack effective protection (*Mora et al., 2006*). In developing countries, greater emphasis is given to incorporating more traditional management methods, such as rotational closures, as they are more likely to be accepted by local communities (*Cinner and Aswani, 2007*).

Data are slowly emerging that marine protected areas eventually work, especially when they are reasonably large and are well enforced. Fish respond most rapidly to protection, but corals also start to increase with time in some cases (*Knowlton and Jackson, 2008*; *Selig and Bruno, 2010*). The mechanisms are not always entirely clear, but often involve improvement in reef resilience, for example, the ability of reefs to recover from bleaching events or severe storms (*Hughes et al., 2010*).

The ability of reefs to resist threats is also improved; for example, in the Great Barrier Reef, protected areas are less vulnerable to population explosions of crown-of-thorns seastars (McCook *et al.*, 2010), and in the Northern Line Islands, protection appears to reduce the prevalence of coral disease (Sandin *et al.*, 2008; Dinsdale *et al.*, 2008). Marine protected areas work even better when coupled with other management measures, such as efforts to improve water quality.

The restoration of damaged reefs is also an option (e.g., Lirman *et al.*, 2010). Methods typically involve growing coral fragments or recruits and placing them on damaged reefs. Although this can be effective in some circumstances, restoration is doomed if the factors that originally killed the corals are still present.

Dealing with Greenhouse Gas Emissions

Climate change models predict that tropical sea surface temperatures will continue to rise and pH will continue to fall. If these scenarios are correct, then bleaching will be more frequent, more prolonged, and more lethal, and corals will find it harder and harder to lay down their skeletons (Hoegh-Guldberg *et al.*, 2007). These predictions are not for the distant future, but for the near future, only a few decades away. The coral holobiont does have some ability to adapt to these threats (e.g., some corals and zooxanthellae are more heat tolerant), but the potential for adaptation is limited, particularly given the rapid rate of global change. Although coastal zone management practices are critical in protecting the well-being of coral reefs in the near term, especially near population centers, over this century, global climate change and how humans mitigate this anthropogenic stress will determine the long-term survival of the most diverse marine environment on Earth.

This article is a revision of the previous edition article by James A. MacMahon, vol. 2, pp. 37–59, © 2001, Elsevier Inc.

Glossary

Alluvial fan Fine sediments deposited by water that form a conical fan when laid down by streams or rivers.

Annual A plant, sometimes called an ephemeral, that survives year to year as a seed rather than as a “plant.”

Convergence or convergent evolution Species develop similar behavioral, physiological, or morphological characteristics in response to living in similar environments in different places.

Desertification Process of changing a nondesert area into what appears to be a desert, regardless of the climate. This process often has a negative connotation relating it to overgrazing by domestic animals, or general human misuse; however, factors, not related to humans, may cause desertification.

Hadley cell A pattern of air circulation that causes deserts at about 30° N and 30° S of the equator. Sun heats the equator, air rises, pressure decreases, moist air moves north and south, cooling as it goes and falls onto the spinning earth, drying as it falls. The falling dry air increases pressure preventing the incursion of moist air.

Life-form A system of classification of the plants in communities based on the position of their perennating structures relative to the ground.

Mesic Moist, but not wet, environment.

Perennating structures The tissue that carries a plant into a new growing season. For example, buds of trees, shrubs, etc., bulbs of some plants (e.g., tulips) or seeds of annuals where the “plant” dies each year.

Physiognomy The general appearance of an area. For example, if you are in any desert in the world it has a certain recognizable “look,” regardless of species composition.

Saltation Sand particles jumping across the surface due to wind movement.

Torpor A condition, usually in birds and mammals, when the body temperature falls a few degrees below ambient for a short period of time. Differs from hibernation in (a) the amount the body temperatures fall and (b) the length of the resting state.

Xeric A dry environment.

The Desert Biome

Seen from outer space, the earth is spotted by a series of conspicuous ochre areas that run in an east–west direction, parallel to the equator at 25–35° latitude in both the northern and southern hemispheres (Figure 1). The reddish-brown blotches are the midlatitude, vegetation-barren deserts that lie some 2000–4000 km away from the equatorial rainforests. In the northern hemisphere, the succession of midlatitude subtropical deserts is formed by (1) the Mojave, Sonoran, and Chihuahuan Deserts in North America, (2) the Sahara’s immense swath in Northern Africa and the Somali-Ethiopian deserts in the Horn of Africa, and (3) the deserts of Asia, including the Arabian, Mesopotamian, Persian, and Thar deserts that cover all the way from the Middle East into Pakistan and India, as well as the Central Asian deserts in Uzbekistan, Turkmenistan, and the Taklimakan and Gobi deserts in China and Mongolia. In the southern hemisphere, the chain is formed by (1) the Atacama, Puna, and Monte Deserts in South America, (2) the Namib and the Karoo in southern Africa, and (3) the vast expanse of the Australian deserts (Allan *et al.*, 1993; McGinnies *et al.*, 1977; Pipes, 1998; Ricciuti, 1996).

There are many criteria to define a desert but perhaps the most important one is aridity – the lack of water, as the main

factor limiting biological processes. Aridity can be measured through several approaches, one of the most common ones is through the “Aridity Index” (Figure 2(a)), the ratio between mean annual precipitation (P) and mean annual potential evapotranspiration (PET , the amount of water that would be lost from water-saturated soil by plant transpiration and direct evaporation from the ground, calculated as a function of temperature and insolation; Thornthwaite, 1948). Arid and hyperarid regions have a P -to- PET ratio of less than 0.20; that is, rainfall supplies less than 20% of the amount of water needed to support optimum plant growth (UNEP, 1997; FAO, 2004). Aridity is highest in the Saharan and Chilean-Peruvian deserts, followed by the Arabian, East African, Gobi, Australian, and South African Deserts, and it is generally lower in the Thar and North American deserts. Aridity index values in the different deserts in the world fall within the arid and hyperarid categories, which can be used as a good first approximation to the boundaries of the Desert Biome (Table 1).

A second approximation to map the Desert Biome is based on biological adaptation (Figure 2(b)), and considers all the global ecoregions that harbor desert vegetation (identified by the xerophilous life-forms and the general desert-adapted physiognomy of the dominant plants). An adequate source for this is the World Wildlife Fund’s (WWF’s) ecoregions of the world report (Olson *et al.*, 2001).

Figure 1 The Desert Biome, enclosed by a yellow line, is clearly discernible in this satellite image of the earth, both north and south of the equator, as a series of ochre-colored patches.

A third criterion to define deserts can be derived from land-cover data in Advanced Very High Resolution Radiometer (AVHRR)-satellite images of the world (**Figure 2(c)**). Using the Normalized Difference Vegetation Index (NDVI) land-cover values, the earth has been classified into different categories (GLOBIO, 2005; USGS, 2005). By this tool, a desert can be defined as an extensive region with little or no vegetation cover (the definition must exclude urban areas, as well as high altitude and polar regions, where low vegetation cover is not due to water limitations).

Each of these approaches may have their own sources of error and the three differ in their definition of what is a desert. However, the three alternative definitions coincide remarkably (**Figure 3**). The Desert Biome, in short, is formed by a set of geographic regions characterized by (1) extremely high aridity, (2) plants and animals showing well-defined evolutionary adaptations to survive in extremely dry environments, and (3) low plant cover and large proportions of bare soil.

Latitudinal Desert Belts

Deserts occur mostly in specific latitudes (25–35° N and 25–35° S of the equator) because of the general thermodynamics of our planet. Solar radiation hits the earth with highest intensity near the equator. Because the earth's axis is tilted 23.5° with respect to the plane of its orbit, during part of the year the zone of maximum solar interception shifts northward, toward the Tropic of Cancer, and during part of the year it moves southward, toward the Tropic of Capricorn. Thus, the warm tropics form a belt around the equator from latitude 23° N to latitude 23° S, where the tropical heat generates rising, unstable air. As it climbs, the air condenses the moisture evaporated from the warm tropical seas and forests, and produces the heavy downpours that characterize the wet tropics. As it moves away from the equator at high altitudes, the air cools again and eventually starts descending in the midlatitudes, some 3000 km away from the equator both

north and south. This closed, low-latitude pattern of atmospheric circulation north and south of the equator is called the "Hadley cells." The air masses compress and heat in their descent and, having lost their moisture during their tropical ascent, they become extremely dry. Thus, by contrast with the equatorial forests, the midlatitude arid fringes that run alongside the tropical belt have a more stable atmosphere; these are the "horse" latitudes, where calm, dry air often dominates. Additionally, because of the stable atmosphere, not only winds are slack but also rainstorms seldom develop. For this reason most of the world's large deserts occur along the belt that separates the tropics from the temperate regions (Goudie and Wilkinson, 1977).

Inland Deserts

The sheer size of continents may be in some cases a direct source of aridity. Because most of the water in the atmosphere is ultimately derived from evaporation from the seas, an aridity gradient develops in large continents when the land closer to the sea receives a larger share of this ocean-derived water and, as air moves inland, it gets depleted of moisture and precipitation drops. Thus, regions lying deep within a continent may become deserts simply because air currents reaching them have already traversed vast land distances and lost most of the moisture they originally carried. Continentality is a major factor driving arid conditions in the Taklimakan and Gobi deserts of central East Asia, the central deserts of Australia, the Great Basin in North America, and the Monte Desert of South America (**Figure 4**). Continentality not only affects the precipitation regime of inland deserts, but also drives the temperature variability. Because of the higher thermal inertia of oceans compared to continental land masses, coastal deserts have a much lower temperature gradient throughout the year than deserts far from the sea (**Figure 5**).

Figure 2 The Desert Biome defined by three alternative criteria: (a) Arid and hyperarid regions of the planet as defined in the World Atlas of Desertification (UNEP, 1997); (b) global ecoregions of the world (Olson *et al.*, 2001) that harbor desert vegetation; and (c) contiguous regions of extremely low vegetation cover derived from AVHRR satellite images of the world (USGS, 2005).

Coastal Deserts

The latitudinal explanation, however, does not account entirely for the global distribution of deserts. Around the mid-latitudinal belt, the western coastal fringes of continents are normally occupied by deserts, while the eastern sides are covered by forests. In North America, the western coast of the continent is occupied by the dry deserts of Baja California, while the east harbors the humid tropical ecosystems of Florida. In South America, the Atacama Desert in the west is

matched by Brazil's luxuriant Atlantic Forest at the same latitude on the Atlantic coast. The Namibian Desert, on the western coast of southern Africa, is paralleled by lush forests on the eastern coast.

The reason for this has to do with the global circulation of ocean currents: gravitation from the sun and the moon pulls air and water on the earth's surface and tends to make them lag behind relative to the earth's rotational movement. The gravitational drag is greatest in the equator, where the centrifugal speed of the earth is fastest. Thus, as the earth turns,

ocean currents and winds flow in the equator from east to west, forming the equatorial currents and the easterly trade winds. As the west-bound surface waters move away from the continents, they pull temperate currents toward the equator along the eastern side of the large oceans, and drag cold, nutrient-rich waters to the surface inducing a cool, stable coastal atmosphere with little evaporation from the sea and very low rainfall other than morning fogs. In the coasts neighboring these oceanic upwellings, typical coastal fog deserts tend to develop, forming some of the driest ecosystems on earth. Thus, the large-scale circulation of the ocean is the main reason why coastal deserts are always found in the west coasts of continents, such as the Namib in Africa (Figure 6), Atacama in Chile, the Atlantic Coastal Desert of Morocco, or the deserts of Baja California (Figure 7).

Rainshadow Deserts

Topographic heterogeneity also contributes to the formation of deserts. Moisture-laden winds decompress and cool in their ascent as they climb continental mountain ranges, condensing

fog and drizzle that feed montane cloud forests. Once the winds pass over the mountain divide, they start compressing and warming-up in their descent, but, having left behind their original moisture, they become hotter and dry. Thus, while the windward slopes of many mountain ranges are covered by cloud forests, the leeward part, known as the “rain shadow” of the mountains, is covered by arid scrub. The rain shadow effect is largely responsible for many arid lands that seem to defy the rule that deserts are found in the earth’s midlatitudinal reaches. Mountain rain shadows are the cause of tropical drylands such as the Sechura Desert in Peru and Ecuador, the Caatinga scrub in equatorial Brazil, or the Tehuacán Valley desert in southern Mexico. Similarly, they are also responsible for some high-latitude cold drylands, such as the large deserts of Central Asia, the Great Basin, and Patagonia.

Desert Landforms

The landforms of deserts, like those of high mountains and the polar areas, are much more visible than those of more vegetated landscapes. Bareness also allows much more active surface processes in all these areas, but in different combinations. Deserts suffer more wind erosion than any other environment, and, if slopes are steep, may also experience very fast water erosion during the short but intense rain pulses.

Desert landscapes come in two categories: (1) “shield” deserts and (2) “mountain-and-basin” deserts (Cooke *et al.*, 1992; Mabbutt, 1977). Shield deserts have developed on very ancient rock basements that have been folded, faulted, and hardened by heat and pressure over millions of years. The Sahara, the Arabian deserts, the southern African deserts, and the Australian deserts are in this group. In many places (as at Uluru in Australia), granite rocks formed originally deep within the earth have been uplifted by tectonic forces and

Table 1 The hyperarid and arid regions of the world – defined as those areas with an aridity index (P/PET) lower than 0.2 – cover in total some 36.2 million km^2 , and occupy almost 20% of the terrestrial surface of the planet. Potential evapotranspiration (PET) is calculated from Thornthwaite’s equations as a function of mean monthly temperatures and mean monthly number of daylight hours, while precipitation (P) is measured directly from weather stations

Classification	Aridity Index (P/PET)	Area ($\text{km}^2 \times 10^6$)	Area (%)
Hyperarid	< 0.05	10.0	7.5
Arid	0.05–0.20	16.2	12.1

Figure 3 The Desert Biome defined by three criteria in combination; that is, aridity, ecoregional physiognomy, and soil cover (see Figure 2). The intensity of the red color indicates congruency between the three criteria: Areas in intense red correspond to regions where the three criteria coincide, areas in intermediate color highlight regions where two criteria coincide, and areas in pale red show areas where only one criterion operates.

Figure 4 Continentiality and aridity: Following a transect along the flat Argentine Pampas from the Atlantic coast to the foothills of the Andes, mean annual rainfall decreases as a function of the distance to the coast at a mean rate of approximately 1 mm of rainfall per km. Because the high Andean Cordillera stops any moisture coming from the Pacific, the continental distance to the Atlantic coast is the single best predictor of precipitation. The colors indicate local weather stations in the humid Pampas (green), the dry Pampas (yellow), and, finally, the Monte Desert (red) in the extreme west.

unearthed by erosion to form steep-sided hills. The basement has been folded into gently sloping swells and basins, and the basins have been filled over millions of years with sediments eroded from the swells. Shield deserts contain ample supplies of groundwater accumulated during past geologic ages, as in the northeastern and southern Sahara, and in Australia; and in some areas they are also rich in oil. Here and there, recent volcanic rocks have overflowed at the surface, as in Ahaggar and Tibesti mountains in the central Sahara. In their long lives, these landscapes have experienced many different climates, partly because they were moved by continental drift, and many features formed in the different climates survive. There are even ancient glacial features in parts of Arabia and the Sahara; there are many ancient river gorges, and ancient wet tropical soils like silcretes or laterites, in what is now a dry desert landscape.

Water is the main agent of erosion on the few hills of the shield deserts and cuts deep gullies on their edges. Elsewhere, low topographic gradients make water erosion ineffective, and the main erosive force weathering these plains is the wind. Great plumes of dust travel from the Sahara toward Europe, southwest Asia and even the Americas and the Caribbean, removing more sediment than do rivers in the same area. With the dust winnowed out by winds, sand is left behind, and most of it collects in dunes, which cover 20–30% of these desert shield landscapes. The median size of these “sand seas” is 123,000 km², but the larger cover more than 300,000 km².

In contrast, deserts in the much more recently folded and faulted rocks of the earth’s active tectonic belts are mountain-and-basin deserts, in which up-faulted mountains alternate irregularly with down-faulted basins. The American deserts, both North and South, belong mostly in this category, as well as the deserts of central Asia (where some of the basins, however, cover many hundreds of thousands of square kilometers). Water erosion in the mountains (which, because of the rainshadow effect, catch more rain than the lower basins) cuts deep, steep-sided valleys and gorges, and takes the debris out to the basins, where the broadening and shallowing of the ephemeral washes (called *arroyos* in the Americas and *wadis* in Northern Africa and the Middle East) causes the coarser debris to be dropped in broad “alluvial fans” (Figure 8). Occasional extreme storms may carry huge boulders onto these as well. Further down-stream, the alluvial fans coalesce into a long slope of finer alluvium – the *bajada*. Sand may be winnowed out of the alluvial deposits and form dunes (and in central Asia, even a few sand seas). Only the finest debris (silt and clay) reaches the bottom of the basin, where it is deposited in ephemeral lakes or *playas*, in which the salts carried in the waters also accumulate in large blinding-white crusts.

Desert Soils

The most extensive soils of deserts are the stony, rocky soils of the uplands (*Leptosols*, in the World Reference Base for Soil

Figure 5 Continentality and temperature range in three hyperarid deserts: data points show mean temperature and mean precipitation for the 12 months of the year. The larger thermal inertia of water relative to dry soil dampens down temperature variations in coastal deserts. As a consequence, annual temperature fluctuations exhibit a range increase as the distance from the sea increases. Arica, in the Chilean Atacama Desert, lies in the Pacific coast and the annual temperature range is only 7 °C; Dakhla, in the Egyptian Sahara, is 520 km from the Red Sea and 590 km from the Mediterranean, and its annual range is 18 °C; while the highly continental area of Turpan, in the north of the Chinese Gobi Desert, is more than 2000 km away from the nearest ocean coast and its annual range is 39 °C.

Resources classification), the sedimentary soils of *bajada* slopes and basins (*Regosols*), wind-blown sands (*Arenosols*), and the gravelly sands of arroyos and wadis (*Fluvisols*). These soils have undeveloped horizons and exhibit only a weakly distinct surface layer, hardly different from the underlying parent material. The most characteristic desert soils are those that exhibit significant accumulations of soluble salts, gypsum, calcium carbonate, or silica. These include *Solonchaks*, characterized by high levels of soluble salts which accumulate naturally in closed depressions; *Solonetz*, highly alkaline, sodium rich soils very slippery when wet; *Gypsisols*, or gypsum

Figure 6 The consequences of the upwelling of cold, nutrient-rich water from the Benguela current near the coast of Namibia are clearly visible in the greenish-white plume of sulfide emissions produced by decomposing phytoplankton accumulated after the winter productivity peak. To the right, the dunes of the Namib desert bear witness to the dramatic aridity of this coastal desert.

soils; *Calcisols*, characterized by accumulation of lime, or calcium carbonate, and *Durisols*, showing a hardpan cemented by dry silica.

Soil surfaces in deserts often have one of two unique characteristics – pavements and crusts. Superficial layer of stones, termed desert pavement, gibber, hammada, or reg, occurs in many deserts, caused by the removal of fine materials by wind or surface water, or by the upward migration of stones. The latter can be caused by a number of physical processes, but most likely causes are cycles of freezing and thawing or of wetting and drying. Often the stones of pavements develop a thin patina referred to as desert varnish.

In some deserts (e.g., southwestern US), 75% of the rock may be covered with desert varnish. The varnish is composed basically of particles of clay with iron and manganese oxides, and its color ranges from red to black depending on manganese content. There is considerable debate about the process of varnish formation. Some scientists believe only physico-chemical processes are involved, while others promote a biological model involving lichens and bacteria. Both processes probably contribute to the variety of colors of varnishes. Surprisingly, desert varnish may form in as little as one or two decades.

The second unique soil surface in deserts is a thin crust-like layer formed by microscopic organisms. When viewed from

Figure 7 Sea surface temperatures in 2–9 June 2001, measured by NASA's Moderate Resolution Imaging Spectroradiometer (MODIS). Cold waters are black, dark green; and blue; purple, red, yellow, and white represent progressively warmer surface waters. Note the plumes of cold water along the Pacific coasts of North and South America (the California Current along Baja California, and the Humboldt Current along the Atacama Desert in Chile and Peru), as well as along the Atlantic coasts of Africa (the Canary Current along the Western Sahara, and Benguela Current along the Namib Desert), which give origin to the main coastal fog deserts of the world. Other coastal and fog deserts are also found around the Arabian Peninsula, in the Red Sea, the Persian Gulf, and the Oman coast, associated to the strong tidal currents in these narrow water bodies and straits.

the side, these crusts are full of vesicles caused by rainfall or perhaps the expansion of soil gases. Crusts that are formed in association with algae and lichens have increased infiltration rates, whereas others may be somewhat water repellant. Most biological crusts involve cyanobacteria, green algae, lichens, and xerophilous mosses. Because some of these organisms are nitrogen fixers, the disturbance of crusts from off-road vehicles, cattle, and human traffic may decrease nitrogen available to plants and impact soil fertility.

Desert Climates

Rainfall Pulses

In deserts, rainfall events trigger short periods of high resource abundance which, despite the overall scarcity of rain, can saturate the resource demand of many biological processes for a brief time. Furthermore, because rainstorms are also frequently very localized, deserts are extremely patchy environments in their resource availability, both in space and in time. Thus, although deserts are characterized often by their mean climatologic conditions (as in the case of the aridity index described previously) they are really driven by a succession of short pulses of abundant available water against a background of long periods of drought. Rainfall pulses are the driving force structuring desert ecosystems, and plants and animals have developed very specific adaptations to cope with ephemeral abundance, especially with regard to growth, population dynamics, and the cycling of organic matter and nutrients (Sher *et al.*, 2004). Within a desert, rainfall events may vary significantly from one pulse to the next. Some spells may occur in winter, others in summer; some events

may bring very little precipitation, others may bring intense showers; and the period between pulses may also vary substantially.

Each desert organism's response threshold is often determined by its ability to make use of moisture pulses of different duration and infiltration depth. For example, brief and shallow pulses have an important effect over surface-dwelling organisms with fast response times and high tolerance for scarce resources, such as soil microorganisms. Short precipitation pulses are important to the survival of annual plants, but deep-rooted perennial plants respond to longer, more intense precipitation events. Thus, the diversity of pulses also promotes a diversity of responses in life-forms, migrations, or population cycles in different species. To a large extent, it is the heterogeneity of pulses that drives the surprisingly large biodiversity of desert ecosystems (Chesson *et al.*, 2004).

But, what commands pulses in deserts? Why are seasons, and even decades, so different from each other, and often so unpredictable? Pulse-type variations in desert environments are linked to global atmospheric and oceanic phenomena. Large-scale drivers of regional precipitation patterns include the position of the jet streams, the movement of polar-front boundaries, the intensity of the summer monsoon, El Niño events, and even longer term ocean cycles, such as the Pacific Decadal Oscillation (Loik *et al.*, 2004). Driven by these large-scale forces, the intensity of midlatitude continentality, ocean upwellings, and rain shadows – the major factors modulating the distribution of arid lands – is not constant but varies from 1 year to the next. As a result, the intensity, frequency, and separation of rain pulses at a local scale may vary substantially through time, often in a seemingly unpredictable fashion.

Figure 8 The basin-and-range topographic sequence is clearly visible at the Laguna Salada in the Mexican Sonoran Desert. The upland mountains discharge their runoff onto alluvial fans of the terraced foothills; down-stream, the water flows in the bajada coalescing into larger streams dotted by mesquite and other phreatophytes (plants that extract water from the deep aquifer), and finally the runoff and drainage water with all its accumulated salts arrives in the valley bottom playa, where it evaporates leaving the salts behind. Thus, the playa salt flat is fringed by a belt of halophytes, or salt tolerating plants. Along these desert topographic sequences, there is an inverse texture effect as compared to wetter regions: soil texture becomes finer toward the valley bottom where the clay is transported by water. The hill slopes are rocky, the foothills are stony, the bajadas are formed by sand and loam, and the playas by clay.

The influence of large-scale drivers on local desert conditions was noted many years ago by the fishermen and the farmers of the coastal desert of Peru, who realized that during some years the normally cold waters of the Pacific became warmer. In these years, they noted, the abundance of sardines decreased but abundant rainfall soaked the land and made the desert flourish. Because this phenomenon was normally observed around the month of December (a time of the year in which Christians commemorate the birth of Jesus, the child – *El Niño* in Spanish), they called the phenomenon “*El Niño*” (technically, “*El Niño Southern Oscillation*,” or ENSO). During *El Niño* years, the trade winds and the west-bound equatorial currents slow down, and the upwelling of nutrient-rich waters in the coasts of the American Continent decreases or ceases. The sea becomes less productive while the coastal fog deserts of the Pacific Ocean become drenched in the abundant rainfall that originates from the now-warm sea waters (Holmgren *et al.*, 2001; Safriel *et al.*, 2006).

These pulses of abundance and scarcity of resources are a major force in the ecological organization of many deserts of the world. During pulses of bounty, the fragile seedlings of desert plants can germinate, establish, and prepare for long droughts by burying their roots deep into the desert soils. Ephemerals can replenish their seed banks (Figure 9); desert

Figure 9 During rainy years, the sand dunes of the Gran Desierto – the driest desert in North America – become lush with the growth of ephemeral plants (Patricio Robles-Gil).

toads can reproduce in extraordinary numbers before entering again into their waterless torpor; and granivorous rodents, such as North American kangaroo rats, Australian hopping mice, and African jerboas, can stock up their underground caches. The desert becomes renewed, and ready to face again years or decades of extreme hardship.

Winter and Summer Rainfall Patterns

Two important weather systems bring precipitation to the world’s deserts. The horizontal transport by wind of moist air from the sea onto the land (known as advective transport) during winter, when the land becomes colder than the sea, causes atmospheric condensation over the cold continents and generates winter rains. Because this particular pattern of summer droughts and winter rains dominates the coasts around the Mediterranean Sea, the areas of the world that show this type of seasonal variation are called “Mediterranean” regions. In summer, in contrast, a different weather system is the main driver of rainfall pulses in arid lands: As the continents become hot they generate low-pressure centers with rapidly ascending warm air (a phenomenon known as convective transport). As the air ascends the atmospheric mass cools rapidly and condenses large amounts of air moisture, which pour down in the form of summer thunderstorms. In many parts of the world this rainfall pattern is known as the “monsoon.”

Most of the large deserts of the world lie between these two weather patterns: The large midlatitudinal deserts often share their boundary with winter-rain ecosystems in their higher latitudes, and with monsoon regions near their tropical reaches (Figure 10). The Sahara Desert, for example, is dominated by winter rains in its northern Mediterranean limit, and by summer rains in its more tropical Sahelian border. The Sonoran Desert, in North America, receives mostly winter rains in its northwestern reaches, near the Mojave, and is fed by the Mexican summer monsoon in its tropical southern reaches (Dimmit, 2000). In South America the Monte Desert receives mostly winter rains in its cold Patagonian austral limit

Figure 10 Rainfall seasonality at high and low-latitude extremes in four different deserts: data points show mean temperature and mean precipitation for each month of the year at weather stations north and south of the large midlatitudinal deserts of the world (Western Sahara, Namib, Sonoran Desert and Monte). All stations lying equator-ward of the desert show increased monsoon-type summer rains while all stations lying more distant to the equator, in the deserts' temperate edge, show Mediterranean-type winter rains.

but is dominated by summer thunderstorms near the Tropic of Capricorn (Ezcurra *et al.*, 1991).

Plants in winter-rain deserts have a rather narrow window of opportunity for growth. During winter, moisture accumulates in the soil but the weather is often too cold for plant growth. During summer, temperature may be adequate but the soil is parched and waterless. Only during spring, when temperatures start to rise and moisture is still present in the ground, can plants flourish. For perennial plants, retaining the leaves from the previous year gives the shrubs an early start and a competitive edge during the short spring. But in order to keep the foliage on until the next year the leaves have to survive the dry desert summer, when no rains occur and the soil is bone-dry. To avoid water loss during the hot season, many evergreen desert shrubs have developed small leaves, or leaves with a thick, leathery epidermis, and few, small stomata (the pores through which leaves breathe and fix

carbon dioxide). Thus, evergreen shrubs with small and/or tough, leathery leaves are the dominant life-form in winter-rain deserts.

Tough leaves are not the only mechanism through which plants can use efficiently the short desert spring season. The winter-rain deserts of the world are also amazingly rich in short-lived spring ephemerals. These plants survive the scorching summer in the form of seeds, bulbs, or tubers, and quickly sprout during the narrow window of opportunity that the desert spring provides. In contrast with the evergreen shrubs, their leaves are soft and tender, and their stomata are large, allowing the plants to grow very fast when conditions are favorable. One of their most astonishing traits is the lack of any evident adaptations to aridity other than fast growth. Because desert ephemerals complete their life cycles during short periods of abundance, natural selection has favored fast growers and even faster reproducers.

In monsoon deserts, in contrast, rainfall pulses coincide with adequate temperatures for plant growth. Because moisture becomes available at a time in which plants can grow fast, leaf retention is rare and drought deciduousness is a dominant trait in shrubs and trees. In these deserts, perennial plants often show extensive networks of shallow roots, and many plants compete to extract water from the soil immediately after the rain has fallen. Giant fleshy trunks or cactoid succulent stems, adapted to accumulate water, are thus common in summer-rain deserts.

Evolution, History and Biogeography

The Evolution of Modern-Day Deserts

During the last 2 million years – the Pleistocene period – the earth underwent a series of alternate cycles of cooling and warming, induced by variations in the planet's orbit and in the inclination of its axis. During the colder periods – known as the “Ice Ages” – most of the high-latitude regions of the world became covered by massive glaciers, and temperate ecosystems such as cold grasslands and conifer forests shifted toward the equator. Because of the higher proportion of land mass in the northern hemisphere, this phenomenon was more conspicuous in North America and Eurasia, where a large proportion of the continental land mass became covered under the ice sheets.

From the late Pleistocene glacial period to our times significant changes occurred in the climate and ecosystems of the planet. During the Last Glacial Maximum (LGM) period, (25–17,000 years before present (yBP)), large ice sheets and lower concentration of atmospheric CO₂ had given rise to a colder climate and a reduced summer monsoon, resulting in a low global forest cover. The tropical belt narrowed and the deserts moved toward the equator, shrinking in the mid-latitudes, where they were replaced by grasslands, semiarid scrubs, open woodlands, or cold steppes. The ancestors of the modern-day desert biota found refuge in what are now dry subtropical habitats, especially in places where arid conditions persisted under the rain shadow of large mountain ranges, or in areas that are now covered by dry tropical savannas, which were then more arid than at present. The last glaciation ended around 15,000 years ago, when the glaciers retreated, giving place to the warm interglacial period that followed: the Holocene, with our current global climate.

As a general rule, during the LGM the high-latitude border of the world's deserts became colder and wetter than they are at present, while the tropical fringe became drier than it is today. Thus, during the LGM large dunes developed in the southern Sahara-Sahel zone and in the Thar Desert of India, while the Mediterranean coast of Algeria and Morocco became wetter and colder. Similarly, during the late Pleistocene the Chihuahuan Desert of North America harbored woodlands of piñon pines, junipers, and oaks, while the tropical dry woodlands of central Mexico became drier, evolving the rich cactus flora that characterizes the region today.

During the warm early- to mid-Holocene (8000–5000 years BP), the global climate that resulted from glacial retreat brought an increase in the intensity of the monsoon throughout the subtropical arid lands. Lake Chad became a

freshwater inland lake bigger than today's Caspian Sea, in an area that has become a complete desert. Tropical forests and dry woodlands extended around the equator expanding north and south, while deserts moved into the midlatitudes. During that period, the southern African Sahara and the Sahel were much wetter than today, with extensive vegetation cover, thriving animal communities, and numerous human settlements.

Sometime between 6000 and 5000 years BP, there was again a transition to more arid conditions. Mesic vegetation communities disappeared rapidly, lake levels declined dramatically, and highly mobile pastoralist cultures started to dominate the region replacing sedentary lacustrine and riparian traditions. The Liwa region of the United Arab Emirates, for example, experienced phases of sand deposition that lead to the formation of a megadune (up to 160 m high). In North America, the late Holocene transition toward more arid conditions brought the arrival of Mojave, Chihuahuan and Sonoran desert scrub elements from the south, such as the agaves, cacti, ocotillos (*Fouquieria*), and creosote bushes that characterize these areas today.

An explanation for these climatic variations is that changes in incoming solar radiation, associated with slow, gradual shifts in the Earth's orbit (i.e., changes in the tilt angle, eccentricity of the orbit, and precession of the equinoxes), enhanced the strength of the summer monsoon rains at the beginning of the Holocene. These rains, in turn, increased the extent of vegetation cover and wetlands with two major concomitant effects – a reduction in surface albedo (reflectance) and an increased ability to recycle water back to the atmosphere through evapotranspiration. Both effects helped fuel the monsoons with additional energy and moisture, increasing the summer rains. In Africa, the climate–vegetation system maintained a “green Sahara” climatic regime through the middle Holocene, when a sudden transition occurred to a “desert Sahara,” the regime that we know at present. The aridization trend of the mid-Holocene fed back into the deserts themselves by decreasing vegetation cover, reducing local inputs of moisture into the atmosphere, and further increasing the dry conditions.

The Formation of Sky-Islands

When the ice sheets started to retreat, some 20,000 years ago, most of the temperate flora and fauna slowly shifted back into higher latitudes and the Desert Biome gradually expanded across the midlatitudes to its current extent. A subset of the temperate biota, however, stayed behind in the rugged and cool mountain ranges that emerge from the desert plains. Establishing higher-up with each passing generation as the climate warmed, the ice-age organisms were able to persist in the cool mountain environments, where conditions are similar to the ones they had enjoyed in the lower plains during the Ice Ages. As they ascended into the isolated desert mountains, the communities of the desert “sky-islands” became separated from other mountains by harsh desert plains. Like prehistoric castaways, the Ice Age species now survive high-up in the cool refuges of the desert mountains; a biological memory of past evolutionary history subsisting high-up in the mountains like ghosts of climates past. And, because they have been

reproducing in isolation for 15,000–20,000 years, many of their populations have developed unique genetic traits and have evolved into new species or subspecies. Thus, in a similar fashion to evolution in remote oceanic islands, the biota of the desert sky-islands is composed by a large number of endemic taxa and has immense value for biological conservation (Axelrod, 1950).

As the effect of the Ice Ages was more severe in the more land-covered northern hemisphere than in the more oceanic southern half of the globe, most of these Pleistocene montane relicts are found north of the equator. In North America, where the desert relief is highly folded, mountainous sky-islands dapple the central part of the Sonoran and the Chihuahuan Deserts, and of the Great Basin. All these ranges contain endemic pines, oaks, madrones, and chaparral species, remnants of the “Madrone-Tertiary” flora, a unique temperate ecosystem that covered much of the now-dry North American deserts during the last 6 million years.

In Africa, similar relict mountains emerge from the harsh Saharan plains: near the Mediterranean coast, the Atlas Mountains in northern Morocco shelter rich pine and oak forests. Further south, the Ahaggar and Tassili-n-Ajjer ranges of south-eastern Algeria and the Air massif in northern Niger harbor a number of endemic and rare Mediterranean species such as the tarout, the wild olive, and the Saharan myrtle. To the east, the Tibesti mountains in southern Libya hold some Mediterranean as well as some tropical relicts. These Saharan mountains also provide prime habitat for migratory birds and a key refuge for threatened wildlife.

In the Somali Peninsula, and across the Gulf of Aden in the southern part of the Arabian Peninsula, high mountain ranges shelter similar temperate relicts: along the northern Somalian coast, in the tip of the Horn of Africa, the Somali Montane Woodlands thrive along the coastal ranges fed by moisture brought in from the sea. A biogeographic refuge and center of endemism, these mountain habitats harbor many endemic species of both plants and animals. The higher part of the ranges contains an evergreen scrub quite similar to the Mediterranean maquis, with species such as kadi, mountain ox, Ethiopian pistachio, and remnants of ancient juniper forests.

Across the Aden Straits, and overlooking the coast of the Red Sea, the high Asir mountains of Yemen and Saudi Arabia give shelter to an even richer relict montane ecosystem with juniper, bramble, and zaytoon olive. Fed by the coastal fogs of the Red Sea, the region shelters more than 170 endemic plants, and is a critical refuge for a large number of endangered animals such as the Arabian leopard and the Hamadryas baboon. Finally, in the eastern part of the Arabian peninsula, near the coast of the Gulf of Oman, the Al Hajar Mountain range forms a spectacular wall of mountains that rise almost 3000 m from the surrounding deserts, providing an important refuge for endemic and relict species of plants of Mediterranean and Indo-Iranian origin, often growing in the vicinity of tiyu (a carob relative) and other trees of African ancestry. The endemic Arabian tahr, a type of wild goat, is still frequent in these precipitous slopes.

These mountains, and many others, play an immensely important role in the maintenance of desert diversity and in the conservation of desert biota. Sharp ecotones exist between

Figure 11 The Maderas del Carmen range in the Chihuahuan Desert is a prime example of a montane Pleistocene relict, or desert “sky island”. The lowlands are covered by creosote bush (*Larrea tridentata*) and prickly pears (*Opuntia* sp.), two hardy desert perennials, but high-up in the mountains the ancient pine forests that once covered a large part of the region still survive (Jaime Rojo).

arid plains and island-like, desert-surrounded mountains. In these slopes, altitudinal change reflects evolutionary time and in their intense transitions it is possible to explore the evolutionary history of deserts during the Pleistocene (Figure 11).

Distribution and Characteristics of World Deserts

True deserts are unique, highly adapted natural ecosystems. The desert biome includes arid and hyperarid drylands, both providing ecosystem services and supporting human populations that may degrade the land resources in much the same ways as in other ecosystems. The deserts of the world occur in six of the world’s large biogeographic domains, or eco-realms. A detailed description of each desert ecoregion within these realms can be found at National Geographic’s Wild World website (www.nationalgeographic.com/wildworld/terrestrial.html) and at the World Wildlife Fund’s terrestrial ecoregions website (<http://www.worldwildlife.org/science/ecoregions/biomes.cfm>). A short narrative description of the world’s main deserts is given in the sections that follow.

Afrotropic Realm: Deserts of East and Southern Africa

The Afrotropic deserts comprise four large lowland desert ecoregions (Ethiopian xeric grassland and shrublands, Nama Karoo, Somali *Acacia-Commiphora* bushlands and thickets, and Southwestern Arabian foothills savanna); eight ecoregions occupying coastal desert fringes (Arabian Peninsula coastal fog desert, Eritrean coastal desert, Gulf of Oman desert and semidesert, Madagascar spiny thickets, Namib desert, Northern Namib’s Skeleton Coast, Red Sea coastal desert, and Succulent Karoo), and four montane Pleistocene relict ecoregions, or desert “sky-islands” (Al Hajar montane woodlands, Ethiopian montane forests, Somali montane xeric woodlands, and Southwestern Arabian montane woodlands). They cover in total 2.7 million km², of which some 10% is under

environmental protection. Their mean population density is 21 persons km⁻², and their mean human footprint index (20; see Sanderson *et al.*, 2002) is moderate on average, but relatively high in the Horn of Africa and Madagascar.

Among the plants that are unique to these deserts are *Welwitschia mirabilis* of the Namib; a great variety of woody legumes and succulent-stemmed species such as baobabs (*Adansonia*), commiphoras or myrrh-trees (*Commiphora*), bottle-trees (*Pachypodium*), and kokerbooms (*Aloe dichotoma*). The Succulent Karoo, which shelters many of these plants, is the world's only plant hotspot (Myers *et al.*, 2000) that is entirely found within the desert biome and is entirely arid. The Madagascar thorny thickets represent a unique, very diverse assemblage of plants and animals, most of them not found anywhere else – such as the local baobabs and the octopus tree (*Didierea madagascariensis*). Much of the Namib is protected but some significant areas are at risk because of prospecting and mining of diamonds and copper. In contrast, very little of the Madagascar thorny thickets are protected, and more than 90% of its original habitat has disappeared through extraction of wood for firewood and charcoal, grazing and clearance for farming. Browsing by livestock and firewood collection by humans also threaten the deserts around the Horn of African and in the southern Arabian Peninsula, from the Red Sea to the Gulf of Oman.

Australasian Realm: Deserts of Australia

The deserts in the Australasian realm comprise 10 flat, lowland ecoregions in WWF's classification (Carnarvon xeric shrublands, Central Ranges xeric scrub, Gibson desert, Great Sandy-Tanami desert, Great Victoria desert, Nullarbor Plains xeric shrublands, Pilbara shrublands, Simpson desert, Tirari-Stuart stony desert, Western Australian Mulga shrublands), covering some 3.6 million km², of which around 9% is under some sort of environmental protection scheme. Hardly inhabited at all, their mean population density is less than 1 person km⁻². These deserts show, by far, the lowest human footprint of the global biome.

All the arid ecoregions identified in Australia receive only sporadic rain and carry sparse vegetation but each one presents its own peculiarities. The Gibson Desert, the “great undulating desert of gravel,” is an area of red gravel soils with mulga (*Acacia aneura*) accompanied by other drought-resistant shrubs and hardy spinifex (*Triodia*) grass. The Central Ranges xeric scrub has low myall and desert oak woodlands growing over spinifex on the sand plains, whereas, throughout the ranges, a profusion of endemic ferns, reeds, and rushes grows in gorges where there is abundant water. The Great Sandy-Tanami Desert is an extensive area of reddish sand plains out of which rises the great Uluru (Ayers' Rock); the plains are covered with clumps of spinifex and scattered saltbush (*Atriplex* spp.) with sparse, spiny acacias and tall desert oaks (*Allocasuarina decasneana*). The vegetation in the Great Victoria Desert is restricted to the hardiest of species, such as spinifex. The dunes and sand plains of the Simpson Desert carry sparse shrubs and spinifex with cane grass (*Eragrostis australasica*) on the deep sands along the crests of dunes, and coolibah (*Eucalyptus* sp.) snaking across the northeastern

corner. The Tirari Desert is characterized by vast sand dunes that harbor an abundant and diverse fauna, an array of unique creatures that have adapted to the high temperatures and soil aridity (marsupials, lizards, frogs, and even small parrots); important fossil deposits have been discovered in the area. Over the Tirari-Sturt Stony Desert sparse saltbush sustains sheep grazing, while its southern portion is woodland with native cypress, black oak, and eucalyptus. Both the Gibson and the Great Sandy-Tanami Deserts are extensive rangelands, mostly uninhabited but supporting important mining activities at the Tanami. Threats include overgrazing, feral, and exotic animals, in addition to the localized and sometimes severe disturbances caused by tourism and mining.

Indo-Malay Realm: Deserts of India and Pakistan

The Indo-Malay region harbors only two hot lowland deserts – the Indus Valley and the Thar – covering 0.26 million square kilometers, of which some 20% receives some level of legal environmental protection. In terms of population, these are the densest and most heavily used deserts in the world, with a mean of 151 persons km⁻²; while their mean human footprint (33) is the highest in the desert biome. These deserts receive 10 and 80 mm of annual rainfall respectively, enough to support trees, shrubs and grasses, in particular *Halostachys caspica* on salty soils and *Aristida pennata* on sandy ones. The rural population depends mostly on raising sheep and goats. About 63% of the Indus Valley and 17% of the Thar Desert are protected (the latter in 11 different spots).

Nearctic Realm: Deserts of North America

The Nearctic deserts are formed by five lowland deserts (Chihuahuan desert, Sonoran desert, Mojave desert, Great Basin shrub steppe, and Meseta Central matorral); two coastal deserts (Baja California desert and Gulf of California xeric scrub), and four montane relict sky-islands (Western Madrean Archipelago, Eastern Madrean Archipelago, Great Basin montane forests, and Sierra de Juárez and San Pedro Mártir pine-oak forests). They cover 1.7 million km², of which 19% is under some level of legal protection. Because of the growth of large urban conglomerates such as Phoenix in the US, their mean population density is high (44 persons km⁻²) and their mean human footprint (21) is the second highest of the world's deserts.

These deserts present a combination of sagebrush (*Artemisia tridentata*) and creosotebush (*Larrea tridentata*) shrublands, halophytes (such as *Atriplex confertifolia*), and open grasslands in the moister parts. There are numerous cactus species except in the Great Basin shrub steppe, where freezing temperatures limit cactus growth. The giant saguaro cactus is emblematic of the Sonoran Desert; it grows very slowly but may reach a height of 15 m over its long lifespan of more than 200 years. The Baja California desert is home to over 3500 species of endemic plants, almost a quarter of which are endemic, ranging from a diversity of shapes and sizes of cacti, to thick-stemmed trees and shrubs in the rocky mountain soils. Likewise, around 1000 of the 3200 plant species in the Chihuahuan Desert are endemic, while creosote bush, tarbush,

viscid acacia, yucca, and cactus are characteristic. The Joshua tree (*Yucca brevifolia*) is probably the most recognizable plant of the Mojave; growing with a wide variety of cacti, creosote bush, white bur-sage (*Ambrosia dumosa*), jojoba (*Simmondsia chinensis*), and small trees such as paloverde (*Parkinsonia microphylla*) and ironwood (*Olneya tesota*). Grazing, hunting and salt extraction (in the Baja California desert) are significant anthropic activities in these ecoregions, which also contain several large and fast-growing cities: Las Vegas, Reno, and Salt Lake City in the Great Basin, Los Angeles near the Mojave, Phoenix and Tucson in the Sonoran Desert.

Neotropic Realm: Deserts of South America

The Neotropic deserts comprise two lowland deserts (Argentine Monte and High Monte), a high-altitude inland desert (Central Andean Dry Puna), and two coastal deserts (Atacama and Sechura deserts). They cover 1.1 million km², of which only 6% receives legal protection. Their mean population density is 18 persons km⁻², and their mean human footprint (16) is lower than in their North American counterparts, with most pressure concentrating in the Sechura Desert along the Peruvian coast. These deserts form a long arid continuum that cover South America's "arid diagonal", starting from the Pacific Ocean just south of the equator in Peru, and running in a southeast direction to the Atlantic coast of northern Patagonia, at latitude 43° S.

The barren landscape of the Atacama Desert is representative one of the driest deserts on earth. The almost complete absence of vegetation in its interior is due to the lack of precipitation and the high mineral content of the soils. Rare rainfall events cause ephemeral plants to germinate and burst with flowers for a short period of time. The Monte, east of the Andes, is a fold desert with sandy plains, plateaus, and rocky foothills with an open, low thorn-scrub harboring a characteristic endemic flora of zygophylls (family Zygophyllaceae). There are also edaphic communities of many species such as *Prosopis* thickets in ravines, shrublands of broom rape (*Baccharis*) and saltbush (*Atriplex*) on clay soils, and *Allenrolfea vaginata* and *Suaeda divaricata* in salty soils. The dry Central Andean Puna carries tall tussocks of bunchgrass and other high-altitude grasses, shrubs like *Parastrephia lepydophylla* and *Baccharis*, and a unique flora of high-altitude cushion plants. The main land use in the Puna is grazing with llamas, alpacas, goats, and sheep. In ancient, pre-Hispanic times, these deserts were an important part of the Inca Empire; a network of roads stretched through them forming the *Qhapaq ñan*, or *Camino del Inca* (the Inca Road).

Palaearctic Realm: Deserts of Central Asia, the Middle East, and Northern Africa

By far the largest set of deserts in the world is found in the Palaearctic realm. The region includes 21 lowland desert ecoregions that cover an immense corridor of deserts stretching from the Atlantic coasts of Morocco, to the Mediterranean coasts of the Sahara, to the Gobi in Central Asia, including the deserts of Northern Africa, Arabia, Azerbaijan, Taklimakan, Central Persia, and the Caspian lowlands (the full list of

ecoregions includes Alashan Plateau semidesert, Arabian Desert and East Sahero-Arabian xeric shrublands, Azerbaijan shrub desert and steppe, Badkhyz and Karabil semidesert, Caspian lowland desert, Central Asian northern desert, Central Asian southern desert, Central Persian desert basins, Eastern Gobi desert steppe, Gobi Lakes Valley desert steppe, Great Lakes Basin desert steppe, Junggar Basin semidesert, Mesopotamian shrub desert, North Saharan steppe and woodlands, Qaidam Basin semidesert, Red Sea Nubio-Sindian tropical desert and semidesert, Registan-North Pakistan sandy desert, Sahara desert, South Iran Nubio-Sindian desert and semidesert, South Saharan steppe and woodlands, and Taklimakan desert). The Palaearctic realm also harbors three coastal deserts (Atlantic coastal desert, Persian Gulf desert, and Red Sea coastal desert), as well as five montane sky-island relict ecosystems (Tarim Basin deciduous forests and steppe, Kuh Rud and Eastern Iran montane woodlands, Afghan Mountains semidesert, Tibesti-Jebel Uweinat montane xeric woodlands, and West Saharan montane xeric woodlands). The Palaearctic deserts cover a remarkable 16 million km², totaling 63% of all the deserts on the planet. Of this area, 9% is legally protected. Their population density is 16 persons km⁻², and their mean human footprint (15) is the second lowest in the planet, possibly because of the sheer inaccessibility and the extreme aridity of many of its large ecoregions.

The great shield desert of the Sahara has immense dune fields covering 33% of the total area, plains of metasediments (sediments or sedimentary rocks that have been subject to metamorphism), and sky-islands, mostly on volcanic rocks in the Tibesti, Ahaggar, and Air ranges. The Red Sea rift separates the Sahara from the Arabian Peninsula, which dips toward the Persian Gulf. The deserts of the Middle East and Central Asia are all rain-shadow deserts, mostly encircled by young fold mountains. The Sahara alone occupies 4.6 million km², or 10% of the African continent. It includes an undisturbed hyperarid central area of sand and rock, but with small areas of permanent vegetation. Vegetation tends to be much more diversified in the Western Sahara, with xerophytes and ephemeral plants in the open desert plains, and halophytes in the moister areas. Currently the Sahara Desert is not well protected legally, but its sheer inaccessibility plays a major role in conserving its ecosystems. The nomadic population depends on pastoral activities, hunting, and trade. Most settled people along the desert fringes do not venture into its interior. The high mountains shelter wild ancestors of many trees that have been domesticated for their fruits and nuts, such as pistachio and wild olive. Considering the hyperarid conditions, the fauna of the Sahara is relatively rich, with 70 mammal species, 20 of them large; 90 species of resident birds, and around 100 species of reptiles.

In contrast with the Sahara and Arabian deserts, the deserts of Central Asia exhibit fold mountain slopes cut by steep valleys with mostly ephemeral streams, fringing alluvial fans, and enclosed basins, some of which contain lakes (Caspian and Aral Seas, Lop Nor) or playas. The Turpan Depression in Western China reaches 154 m below sea level. The predominant vegetation types are all formed by typical desert species of the Old World: grasses such as *Panicum*, *Poa*, and *Stipa*; sedges (*Carex*); desert bulbs such as wild tulips (*Tulipa* spp.); halophytes such as *Salicornia* and *Atriplex*; and shrubs

such as *Artemisia*, *Euphorbia*, and *Caragana*. The most common vegetation found in the ecoregion is the desert sagebrush and other *Artemisia* species. The range of the flora goes from sagebrush to psammophilous (dune-adapted) plants, and includes salt-tolerant chenopod communities (Chenopodiaceae) in Afghanistan. The salt pans have almost no vegetation. In some parts, the deserts of Central Asia still support small populations of valuable animals like wild Bactrian camels (*Camelus ferus*) and Asian wild asses (*Equus hemionus*) that have been largely extirpated in the wild.

The Mesopotamian shrub desert is transitional between the deserts to the south and the steppes to the north. The flora includes umbrella-thorn acacia (*Acacia tortillis*), shrubby rock-rose species (*Cistus* spp.), and many dwarf shrubs. Reeds and rushes grow in the wetland areas, while poplar (*Populus euphratica*) and tamarisk (*Tamarix*) grow along river channels.

The whole ecorealm has evolved under continual grazing pressure and most plants are adapted to grazing pressure. However, overgrazing is a constant threat. Illegal hunting is a serious threat in the South Iran Nubio-Sindian desert; while egg collection and nest disturbance affect nesting migratory waterfowl. Significant portions of the Azerbaijan shrub desert and the Central Asian Northern desert are farmed under irrigation, bringing on water and soil pollution by the use of fertilizers and pesticides. The region as a whole contains most of the world's oil reserves and large gas reserves, increasingly exploited and with associated urban areas and infrastructure development. The vital ground waters are also under heavy development pressure.

Biological Adaptations to Aridity

At its origins, life evolved in water, and water is the most crucial element for the survival of all living organisms. Thus, it

is no surprise that some of the most remarkable adaptations for survival are found in desert species, that is, in the environments where water is most scarce (Louw and Seely, 1982). The short pulses of abundance that contrast sharply with the background condition of aridity and scarcity are the major force that has driven evolution, natural selection, and adaptation in desert biota. Plants and animals are adapted to these seasonal strokes. Natural selection and evolution have molded in very precise ways the life-forms of desert organisms to their harsh and unpredictable environment. Furthermore, because most deserts of the world have developed in relative isolation from each other, many of their constituent species have evolved from different ancestors (Morton, 1979). Thus, deserts are prime ecosystems to study and understand the phenomenon of convergent evolution – the development of similar growth forms and adaptations derived from different ancestors (Table 2, Figure 12).

Adaptations of Plants to Aridity

Most desert species have found remarkable ways to survive drought (Robichaux, 1999). Desert succulents, such as cacti or rock plants (*Lithops*) for example, survive dry spells by accumulating moisture in their fleshy tissues. They have an extensive system of shallow roots that allows them to capture soil water only a few hours after it has rained. Their photosynthesis is modified to exchange gases and fix CO₂ during the night, when evaporative demand is low, and to accumulate the fixed carbon in the form of malic acid, which is later used by the plant as a building block of more complex organic molecules (this photosynthetic pathway is called “Crassulacean Acid Metabolism” or CAM). Additionally, many cacti and other stem-succulent plants of hot deserts present columnar growth, with leafless, vertically erect, green trunks that maximize light interception during the early and late hours of the

Table 2 Convergent evolution of animal guilds in four hot deserts of the world. In spite of their different phylogenetic origins and their different biogeographic histories, many of these animals look strikingly similar in appearance

Figure 12 The Australian horny devils (*Moloch horridus*, shown in this picture taken in Alice Springs, Australia) are surprisingly similar to the North American horned lizards (*Phrynosoma coronatum*, in Baja California) in both their feeding habits and their ecology. Their similarity, however, is due to convergent evolution in distant deserts, as they belong to different families and are taxonomically unrelated (Patricio Robles-Gil).

day, but avoid the midday sun, when excessive heat may damage, or even kill, the plant tissues. Thus, erect columnar plants may avoid drought by (1) accumulating water, (2) exchanging gases at night, and (3) morphologically avoiding midday exposure to solar radiation (Zavala *et al.*, 1998). Instead of having developed succulent stems adapted for water storage, other CAM plants such as aloes and agaves have developed ground-level rosettes of succulent leaves. Because of the funnel-shape of their leaf-whorls, these plants seem to be adapted to collect dew from morning fogs in desert mountains, hill slopes, and ocean coasts, accumulating the water thus harvested in their fleshy leaves and central bud (Martorell and Ezcurra, 2002).

Woody desert trees, such as acacias, cannot store much water in their trunks but many of them evade drought by shedding their leaves as the dry season sets-in, entering into a sort of drought-induced latency. Many of these desert species also have long taproots that explore deep underground water layers. Other trees have evolved convergently a mixture of these strategies: they can store water in gigantic trunks and have a smooth bark that can do some cactus-like photosynthesis during dry periods; but, when it rains they produce abundant green leaves and shift their metabolism toward that

Figure 13 The fleshy stems of the kokerbooms (*Aloe dichotoma*) – one of Africa's many giant, fleshy-stemmed trees – are true landmarks in the otherwise barren landscape of the Namib Desert (Patricia Rojo).

of normal-leaved plants. This group is formed by trees with famously “bizarre” trunks, such as the African baobab (*Adansonia*), the Baja-Californian Boojum-tree (*Fouquieria columnaris*) and elephant-trees (*Bursera* and *Pachycormus*), and the South African commiphoras (*Commiphora*), bottle-trees (*Pachypodium*), kokerbooms (*A. dichotoma*, **Figure 13**) and botterbooms (*Tylecodon*).

A third group of plants, the “true xerophytes” or true desert plants, have simply adapted their morphology and their metabolism to survive extremely long droughts. These species have remarkably low osmotic potentials in their tissue, which means that they can still extract moisture from the soil while most other plants cannot do so. True xerophytes, such as the creosote bush (*Larrea*), are mostly shrubs with small, leathery leaves that are protected from excessive evaporation by a dense cover of hairs or a thick varnish of epidermal resin. Their adaptive advantage lies in their capacity to extract a fraction of soil water that is not available to other life-forms. However, because their leaves are so small and protected from transpiration, their gas-exchange metabolism is very inefficient during rain pulses when moisture is abundant. In consequence, these species are extremely slow growers, but extremely efficient water users and very hardy.

Finally, one of the most effective drought-survival adaptations for many species is the evolution of an ephemeral life cycle. A short life and the capacity to leave behind resistant forms of propagation is perhaps one of the most important evolutionary responses in most deserts, found not only in plants but also in many invertebrates. Desert ephemerals are amazingly rapid growers capable of reproducing at a remarkably high rate during good seasons, leaving behind myriad resistance forms that persist during adverse periods. Their population numbers simply track environmental bonanzas; their way to evade critical periods is to die-off, leaving behind immense numbers of propagules (seeds or bulbs in the case of plants, eggs in the case of insects) that will restart the life cycle when conditions ameliorate. These opportunist species play an immensely important role in the ecological web of deserts: myriad organisms, like ants, rodents, and birds, survive the dry spells by harvesting and consuming the seeds left behind by

the short-lived ephemeral plants. Granivory (the consumption of seeds) and not herbivory (the consumption of leaves) is at the base of the food chain in most deserts, as those few plants that maintain leaves during dry spells usually endow them with toxic compounds or protect them with spines. The onset of rainy periods brings to the desert a reproduction frenzy of desert ephemerals, and a subsequent seed-pulse that drives the entire food web for years.

Thus, the survival strategies of desert plants are classifiable along a gradient ranging between two extreme categories: (1) adaptation for quick use of ephemerally abundant resources, or (2) adaptation for the efficient use of poor but more permanent resources (Shmida, 1985). The first category, typically exhibited by desert ephemerals, represents a “maximum variance” behavior that consists essentially in tracking environmental variation, while the second category, exhibited by true xerophytes and cacti, is a “minimum variance” behavior that consists in adapting to the worst possible conditions. Drought-deciduous perennials and grasses represent a compromise between the two extremes. Attributes necessary for the quick use of water include rapid growth (often at the cost of low water-use efficiency) and abundant seed production. Attributes for survival with little water include high water-use efficiency, slow growth, and passive cooling. Drought deciduousness, as an intermediate strategy, requires the capacity to shed leaves and to quickly recover them when moisture conditions improve.

The survival strategies of desert plants present some of the most striking cases in nature of evolutionary convergence: Plants from widely different families and from divergent evolutionary origins have developed in the different deserts life-forms so similar that it is sometimes difficult to tell them apart. Such is the case of the succulent cactoid growth form, evolved in Africa in the families Euphorbiaceae, Asclepiadaceae, and Aizoaceae, and in the Americas in the family Cactaceae. Similarly, bottle-trees in Africa evolved in the families Apocynaceae, Aloeaceae, and Crassulaceae, while in the New World they belong to the Fouquieriaceae, Anacardiaceae, and Burseraceae. Superficially, however, they are almost undistinguishable.

Adaptations of Animals to Aridity

Adaptation of animals to desert conditions can be divided into morphological and anatomical, physiological or behavioral. Among the first, in mammals, desert fur coats are short, hard and compact, but at the same time well ventilated, to allow sweat to evaporate directly from the skin. Birds can fluff or compact their feathers to regulate heat exchange. In the ostrich, a desert dweller, the uncovered head, throat, legs and abdomen allow for radiation and convection cooling, while the feathers on the back protect the larger part of the body from direct solar radiation (Figure 14). Bipedalism, a common trait in small desert mammals such as kangaroo rats, allows for fast travel in open spaces and also keeps the body separated from the extreme temperatures of the ground surface. Indeed, bipedal desert rodents use open microhabitats much more frequently than their quadrupedal relatives, who restrict their activities to sheltered habitats.

Figure 14 Despite the grueling heat and extreme drought, a family of ostriches (*Struthio camelus*) survives and thrives in the Namib Desert (Patricio Robles-Gil).

Sand-dwellers have evolved several traits that allow them to survive in dunes, including fleshy foot-pads in camels, scaly fingers in certain lizards and digital membranes in some geckoes. Additionally, camels have long dense lashes that protect their eyes and they can close their nostrils to protect them from wind-blown dust. Many snakes have upwardly turned nostrils that allow them to burrow rapidly in loose sand; others are flat and can bury laterally. Many reptiles show also adaptations that protect their eyes, nose, and ears from sand and dust, and many insects have especially adapted legs that allow them to bury themselves rapidly and to walk efficiently on hot sand.

The most basic physiological problem of desert animals is to maintain their water balance by maximizing water intake and/or minimizing water loss. In deserts, free-standing water is scarce, found only in isolated oases and reservoirs. Camels and wild asses, for example, are able to drink large quantities of water in a very short time, which causes a dramatic dilution of the bloodstream sufficient to cause death in other animals, with no ill effects. In coastal deserts, animals obtain water by licking fog-drenched rocks. Desert amphibians can absorb water through the skin from humid underground dens by accumulating urea in their blood and raising its osmotic pressure.

Most herbivores, like eland and oryx, obtain water from the foliage of the shrubs that compose their diet, often feeding at night when the plants are turgid. Some succulent plants have high salt contents, toxic compounds, or spines to deter their consumption. Herbivores, however, have found their way around these obstacles: some reptiles and birds have developed efficient salt-excreting glands, and many mammals have kidneys that can cope with salty water. White-throated packrats (*Neotoma albigula*), which feed almost exclusively on juicy cacti, have metabolic adaptations to prevent poisoning from the oxalates contained in these plants.

Animals lose water through urine, feces, respiration, and transpiration. Desert rodents have kidneys that are capable of producing highly concentrated urine, with an electrolyte concentration many times higher than that of blood plasma. Reptiles, birds and insects excrete uric acid, which requires less

water, and sometimes complement the excretion process with specialized excretion from salt glands. Amphibians produce little urine, and can store large amounts of urea within their bodies, drastically reducing water loss. In droughts, some rodents can produce dry feces, efficiently reabsorbing liquids in the rectum.

Metabolism produces CO_2 and water as byproducts of respiration. In most animals, this metabolic water is exhaled through the lungs, but many desert animals, including invertebrates, reptiles, and mammals, possess physiological and anatomical adaptations to reduce respiratory water loss, including modifications in the morphology of the nasal passages and the capacity to reabsorb water along the respiratory tract. One of the most extreme examples of this is given by the kangaroo rats (*Dipodomys*), which can survive on a diet of perfectly dry seeds.

In addition to the mechanisms that reduce water loss, many desert animals are extremely tolerant to dehydration, a condition that causes a fatal increase in blood viscosity in nondesert dwellers. To achieve this, camels, for example, are able to lose water selectively from tissues other than blood. In contrast, desert amphibians are tolerant to increased fluid viscosity, and some reptiles can excrete excess electrolytes through urine and salt glands, avoiding the thickening of the blood as they dehydrate. A problem related to dehydration is that of temperature regulation. In smaller animals the high surface-to-body ratio makes sweating a dangerous enterprise and panting is the most common method of cooling. Even larger animals that usually sweat, like the oryx, begin to pant when their body temperature exceeds 41 °C.

Nocturnal hypothermia, exhibited by some large mammals like the eland, allows them to reduce their metabolic rate and to exhale air with less humidity during the night. Diurnal hyperthermia allows animals to reach body temperatures that would be normally lethal for nondesert vertebrates and to save on water needed to prevent overheating. Camels and elands, for example, can reach body temperatures of 44 °C with no harmful consequences, and saving as much as 5–10 l of water during extremely hot days. Hyperthermal species have a special disposition of veins and arteries that allows their brains to remain at a temperature lower than that of the overheated body.

Like ephemeral plants, many smaller desert animals can also evade drought by entering into a dormant phase: Desert butterflies and grasshoppers thrive in huge numbers when conditions are good and survive dry spells in the form of eggs or pupae. Spade-foot toads (*Scaphiopus*) spend most of their lifetime buried in dry mud and become active only after rains refill their ephemeral pools. Many other organisms go into some form of torpor during dry periods.

Behavioral adaptations are many. Numerous birds and most large mammals, like pronghorn antelopes or wild sheep, can evade critical spells by migrating along the desert plains or up into the mountains. Smaller animals cannot migrate such long distances, but regulate their environment by seeking out cool or shady places. In addition to flying to other habitats during the dry season, birds can reduce heat loads by soaring. Many rodents, invertebrates, and snakes avoid heat by spending the day in caves and burrows, and procuring food during the night. Even diurnal animals may reduce their

activities by resting in the shade during the hotter hours of the day. Fossoriality, a lifestyle based in burrows, is the norm for small animals in all deserts, as it allows them to stay away from the grueling heat during the hotter part of the day and it also provides them with a warm refuge during the cold desert nights. Additionally, humidity inside burrows (approximately 30–50%) allows desert animals to preserve water. When the normal mechanisms to prevent increases of body temperature above acceptable limits fail, many small rodents and some desert tortoises (*Testudo*) salivate to wet the chin and throat and allow evaporative cooling. Such mechanism has a high cost in water and is used only as an emergency measure to prevent death.

At dawn, the dry desert ground may approach freezing temperatures and at midday it may heat up into an 80 °C inferno. A few inches above the ground, variations in air temperature are much less pronounced, and, just a few inches below the surface, temperatures are almost constant between day and night. For this reason, thermoregulating is a particularly challenging problem for small surface-dwellers and especially for reptiles, which cannot regulate metabolically their body temperature. Most desert reptiles have developed peculiar ways of travelling over hot sandy surfaces. Side-winding, a form of lateral movement in which only a small part of the body is in contact with the surface, is employed by many sand snakes (Figure 15). Many lizards and some ground birds avoid overheating by running rapidly over the hot desert surface while maintaining their bodies well separated from the ground (Safriel, 1990). Some lizards assume an erect, bipedal position when running, while others regulate their contact with the hot desert pavement by doing “push-ups” with their forelegs. By changing from quadrupedal to bipedal travel, several species move more efficiently as they direct their running force downward rather than laterally (MacMahon, 2001).

Many large mammals that cannot avoid being in the sun during a large part of the day orient their bodies so as to reduce the incidence of the sun’s rays. By standing upright, guarding ground squirrels reduce solar incidence upon their bodies. The African ground squirrel *Xerus inauris* even orients

Figure 15 The characteristic crawling pattern of the sidewinder (*Crotalus cerastes*) leaves a tell-tale trail in the dunes of the Gran Desierto. Its perfect matching to the color of the sand protects it from predators such as kestrels and falcons (Patricio Robles-Gil).

Figure 16 Using its tail like a parasol, the African ground squirrel (*Xerus inauris*) protects itself from the sun in the Namib Desert (Patricio Robles-Gil).

toward the sun and shades itself with its tail when foraging (Figure 16). The jackrabbit *Lepus californicus* warms its body in the early morning by exposing its large, highly vascularized ears perpendicular to the sun's rays, using them as a form of solar collector. Similarly, it cools at midday by keeping in the shade and putting the ears parallel to the incoming solar radiation, thus minimizing exposure while keeping the same radiative surface.

Desert Ecosystem Processes

Primary Productivity and Soil Fertility

Although deserts cover around 22% of the world's terrestrial area, only about 1% of global primary productivity occurs in them. There is a strong correlation between annual net primary productivity (NPP) and precipitation; NPP in extreme deserts ranges from 0 to $10 \text{ g m}^{-2} \text{ year}^{-1}$, and, in shrubby deserts, from 10 to $250 \text{ g m}^{-2} \text{ year}^{-1}$. These low values contrast with those of temperate grasslands ($200\text{--}1500 \text{ g m}^{-2} \text{ year}^{-1}$) and forests ($600\text{--}1500 \text{ g m}^{-2} \text{ year}^{-1}$). In North America, the Mojave Desert is, on average, the lowest producing area with $25 \text{ g m}^{-2} \text{ year}^{-1}$, while average values in the Chihuahuan Desert are close to $120 \text{ g m}^{-2} \text{ year}^{-1}$.

Nitrogen (N), phosphorus (P), and potassium (K) are important nutrients for plant growth and, in arid areas, these nutrients are usually associated positively with shrubs. For

example, in a creosotebush community there were $0.253 \text{ mol of N per kg of soil}$ beneath the canopy and 0.148 and 0.10 at the canopy edge and interspace, respectively. There may be several reasons for this association, the most general one relating to the concept of "islands of fertility." Once established, a shrub sheds leaves (at a rate of $19\text{--}53 \text{ g m}^{-2} \text{ year}^{-1}$) and portions of its belowground roots die adding organic matter to the soil. Additionally, the roots may extend into the barren area between shrubs and extract nutrients from those areas, concentrating them under shrubs. Rodents often make burrows at the bases of shrubs and the addition of their nesting material and digging activities can increase soil nutrients.

Nitrogen is generally scarce in deserts. It enters the system through fixation by organisms in soil crusts, through fixation by the nodules on the roots of woody legumes such as mesquite and acacias, and through airfall deposition. In the past it was thought that low quantities of nitrogen limited primary productivity. More recently, it has been suggested that phosphorus may be more limiting because it is relatively unavailable in the alkaline soils of deserts. When nutrients exist in desert soils, they may not be available because decomposition occurs more slowly in the absence of water, and because the microfauna and microflora that usually affect decomposition are at much lower densities than in forest or grassland systems. None of these decomposers can continue activity when soils are very dry. In the Chihuahuan Desert, termites are extremely important in decomposition, but this seems less so in drier areas, where biological decomposition of organic matter occurs mostly under the protective shade of shrub canopies and grass clumps. In the open bare space, ultraviolet radiation, the same factor that hinders biological decomposition, is the main cause of organic matter degradation. It is solar UV radiation, and not humus-forming microorganisms, that finally weathers and decomposes organic matter in the bare soil of extreme deserts (Montaña *et al.*, 1988).

Interactions Between Species

The harsh conditions of desert ecosystems has promoted the evolution of a complex set of relations among desert organisms, a surprising number of which are positive interactions (Cloudsley-Thompson, 1996). Desert shrubs in general and woody legumes in particular, create microhabitats that are critical for the survival of other species. Small animals seek the shade of desert trees and shrubs, birds find refuge and nesting sites in their canopies, and many small plants recruit their juveniles under the nitrogen-rich canopy of desert woody legumes such as acacias, carobs, and mesquites. Because of their CAM metabolism, desert succulents such as agaves, aloes, and cacti are poor thermoregulators as young seedlings, and cannot survive the harsh ground-level midday temperatures. For this reason, they can successfully germinate and establish only under the protective shade of shrubby "nurse plants" that act as true cornerstone species in desert conservation (Figure 17). If the desert trees and shrubs are cut, all the accompanying biota soon disappears.

Additionally, many desert plants have very specific requirements in terms of their pollinators and seed dispersers

Figure 17 Giant saguaro cacti (*Carnegiea gigantea*) in the Pinacate mountains of the Sonoran Desert establish and grow under the protective shade of a paloverde (*Parkinsonia microphylla*), a legume species that generates true islands of fertility in the harsh desert environment (Patricio Robles-Gil).

(Figure 18). Although some desert ephemerals are truly unspecific in their requirements and produce thousands of seeds with only wind-pollination, the slow-growing desert perennials are frequently highly specialized in their reproductive habits, and depend strictly on coevolved animals to help them out in their sexual and reproductive processes. Many African cactoid plants (euphorbs and asclepias) produce foul-smelling flowers that attract carrion insects as pollinators. New World giant cacti and agaves produce sugar-rich nocturnal flowers that engage the pollinating services of nectar-feeding bats, while the sweet pulp of their fruits lures birds to disperse the seeds miles away. The red tubular flowers of many desert shrubs attract hummingbirds and giant sphinx-moths.

In almost all deserts of the world, three types of granivorous organisms are influential: harvester ants, small mammals, and birds. These organisms disperse or consume seeds, and, in the case of ants and burrowing small mammals, they turn over soil at very high rates, change the physical conditions of the soil through digging activities, incorporate organic matter, and remove vegetation from the sites of their nests. Some bipedal rodents, such as kangaroo rats, dig small surface caches to store seeds, from where new plants may germinate after a pulse of rain. Interestingly, the relative importance of these three groups differs around the world: In North America and Israel, small mammals are most important and remove the greatest number of seeds, followed by ants, and then by birds.

Figure 18 A Gambel's quail (*Callipepla gambelii*) forages on the ripe, red, juicy fruits of the saguaro. After digesting the sweet pulp it drops the seeds, often under the protective shade of nurse plants, where the cactus will be able to germinate and establish (Patricio Robles-Gil).

In the Karoo, ants take more seeds than small mammals, as they also do in the Monte of Argentina. Birds may be quite important seasonally. For some species of plants, nearly 100% of the seeds are removed by granivores while other species lose a very small portion. This differential feeding can clearly alter the composition of the plant community. Additionally, for species like the harvester ants that carry seeds back to their nests and belowground, there are dramatic changes in soil properties where these nests exist. Clearly, soil disturbance and granivory, with its concomitant on seed dispersal, have an important role in structuring desert ecosystems.

Humans in the Desert

"Coevolution" is a term evolutionary theorists use to describe a sort of ecological "intimacy," when the evolution of one organism is shaped by and in turn shapes the evolution of another (Ehrlich *et al.*, 1988). It is interesting to consider the evolutionary trajectories of desert biota and of human beings in that light. Relative to the time-scales of the geologic and atmospheric processes that created desert conditions, the advent of humans is a very recent event. Nonetheless, the effect of humans on deserts – and of deserts on humans – is pronounced.

Desert landscapes and desert biota have had profound effects on human cultural evolution. Humans display

remarkable behavioral and cultural adaptations to the aridity and unpredictability of deserts, and traditions derived there have influenced human and biological communities far beyond the desert edge; that the three “religions of the book” had their origins in these environments well-illustrates that fact (Safriel *et al.*, 2006). Plants and animals from these harsh landscapes have also played an important role in the evolution of modern human societies. Dryland biota provided much of the “raw material” for species that could and did become domesticated, which helped usher in the dawn of pastoral and agricultural societies. The early domestication of ungulates (cattle, sheep, and goats) began in the drylands of the Near East, on the edge of the Arabian Deserts, some 9000 years ago (Davis, 2005), and the domestication of llamas and alpacas took place in the Andean Puna of South America some 6000 years ago just north of South America’s “arid diagonal” formed by the Atacama, Dry Puna, and Monte deserts (Table 3). In many regions of the world, dryland annuals have been at the base of the plant domestication process and drylands have been the cradle of agricultural societies. The first records of cultivated wheat and barley (two dryland ephemerals) come from the Fertile Crescent of the Near East some 7000–9000 years ago. In the American Continent the first agricultural records come from the Tehuacán Valley in southern Mexico, a hot tropical dryland where corn and squash (two annual, drought-tolerant fast growers) were first domesticated some 6000 years ago. Not too long after that, gatherers in the Andean Puna started domesticating two other dryland ephemerals: the quinoa (*Chenopodium*, a fast-growing annual) and the potato (*Solanum*, a tuber ephemeral).

That biota of drylands would be a source of such innovation is not surprising, given the life history of those plants and animals. Arid-land herbivores, in particular desert ungulates, are extremely hardy. They can use water very efficiently, they can withstand long periods without drinking, and when forage is plentiful they can convert plant material quickly into animal protein, with very high efficiency. Furthermore, many of them are migratory and move naturally in herds following a leader, looking for new foraging grounds, and socially protecting themselves from predators. For all these evolutionary reasons, ungulates native to drylands were ideal candidates for domestication: hardy animals, efficient foragers, and amenable to shepherding, as social aggregation

is a natural behavior for them. Some of the same factors that made wild goats, mountain sheep, or guanacos evolutionarily adapted to desert environments are what drove early hunter-gatherers to start breeding their offspring and selecting them for desirable domestic attributes. As with desert ungulates, the same traits that have made some desert annuals apt to survive and thrive on ephemeral water pulses are what make them so apt for agriculture: fast growth, short life cycle, and the capacity to direct most of their metabolic budget toward the abundant production of seeds. Because dryland ephemerals grow so fast and produce so much seed in just a few weeks, they grow at an amazingly fast rate when planted at the desert’s edge and make ideal grain plants, especially cereals and pulses.

The effect of humans on the ecology and the evolutionary trajectory of deserts can be similarly pronounced. The following ecological “anachronism” provides an illustrative example: some desert plants have seed dispersal mechanisms that reflect the existence of seed dispersers that are no longer present. Trees like the mesquites (*Prosopis*), for example, have pods with nutritious sweep pulp and extremely tough seeds, which need intense scarification in order to germinate. Similarly, the tough seeds of the prickly pears (*Platyopuntia*) germinate successfully only when chewed and digested for a long time. During the Pleistocene period, this abrasion was provided by the digestive system of large ungulates, such as gomphotheres or giant ground sloths. At the end of the last glaciation some 15,000 years ago, however, much of that Pleistocene megafauna went extinct – a fate that humans likely contributed to (Martin, 1973; Martin and Klein, 1989; Alroy, 2001; Brook and Bowman, 2004). Loss of that fauna resulted in the loss of seed dispersal and regeneration mechanisms for a number of plant species. Desert plant species with anachronistic seed dispersal have merely survived for the last millennia through vegetative growth and accidental abrasion of seeds in the deserts’ sand and gravel, in the absence of their effective seed dispersers. Not surprisingly, when humans re-introduced ungulates – cattle – into the New World some five centuries ago, the population of many of these plant species rebounded to large numbers.

Humans continue to affect desert ecology, at times fundamentally. Being areas of such low productivity, deserts can be easily degraded – even irreparably – by the increasing intensity of human land and resource use. Desert soils, which are of

Table 3 Domestic mammals evolved from wild dryland ancestors

Domestic form		Wild progenitor		First domestication		Distribution of wild progenitor
Common Name	Scientific name	Common name	Scientific name	Date	Place	
<i>Perissodactyla</i>						
Donkey	<i>Equus asinus</i>	African ass	<i>Equus africanus</i>	4000 BC	Egypt	North Africa, possibly West Asia
<i>Artiodactyla</i>						
Llama	<i>Lama lama</i>	Guanaco	<i>Lama guanicoe</i>	4000 BC	Peruvian Andes	South American drylands
Alpaca	<i>Lama pacos</i>	Guanaco	<i>Lama guanicoe</i>	4000 BC	Peruvian Andes	South American drylands
Dromedary	<i>Camelus dromedarius</i>	Dromedary	<i>Camelus sp.</i>	3000 BC	West Asia	Asia, possibly North Africa
Bactrian camel	<i>Camelus bactrianus</i>	Bactrian camel	<i>Camelus ferus</i>	3000 BC	Central Asia	Central Asia
Goat	<i>Capra hircus</i>	Wild goat	<i>Capra aegagrus</i>	7000–8000 BC	West Asia	West Asia
Sheep	<i>Ovis aries</i>	Mouflon	<i>Ovis orientalis</i>	7000–8000 BC	West Asia	West Asia

generally limited profundity and high fragility, are highly susceptible to compaction, erosion, and salinization when exploited for agricultural, industrial, or recreational purposes. Invasive non-native plants, whether introduced intentionally (such as in the case of the planting of grasses for livestock forage, which have the effect of introducing a grass-fire cycle to an ecosystem that has no natural fire regime) or not (such as the case of the invasion of *Tamarix ramosissima* in Nearctic deserts, which can substantially alter desert hydrological regimes), can have cascading effects on ecosystems function and native species viability in deserts. Human industry in and beyond deserts alters not only desert weather patterns via anthropogenic-induced climate change, but also desert nutrient cycling via atmospheric deposition. Paradoxically, fertilization of deserts through increased deposition of nutrients like nitrogen can favor the invasive dispersal of non-native species and reduce native diversity. Whether through direct or indirect pathways, humans clearly have a hand in determining the future course of desert evolution.

Concluding Remarks

To the untrained eye, deserts look barren, especially during dry periods. However, because of their evolution in relative geographic isolation, most deserts of the world are rich in rare and endemic species, and are hence highly vulnerable to biological extinction and environmental degradation. In spite of their remarkable convergence in adaptation, deserts are different in their origin and their evolutionary history. Their incredible variation of the world's deserts in rainfall patterns, continentality, temperature regime, and evolutionary history have all contributed not only to their biological uniqueness, but also to their wondrous wealth of life-forms and adaptations, from some of the shortest-lived ephemeral plants, to some of the longest lived giant cacti; from seed-eating rodents that do not need water to survive and depend on their burrows to regulate their metabolism almost as if the burrow was an extended part of their body, to amazing pollinators like nectar-feeding bats that migrate thousands of miles following the flowering seasons (Davis, 1998). This adaptive diversity – what Darwin, strongly influenced by deserts himself, called “forms most beautiful and most wonderful” – is what makes deserts unique. In the hot deserts we may find giant cacti and trees with mammoth fleshy stems coexisting with some of the toughest hardwoods; ground-creeping succulents side by side with fog-harvesting rosettes, incredibly fast-growing annuals together with the hardest drought-resistant perennials; shrubs of enticing odors with some of the nastiest, spiniest plants. Very few parts of the earth contain a richer collection of natural adaptations (Ezcurra *et al.*, 2006; Ezcurra and Mellink, 2005).

The fragmented evolutionary history of the deserts of the world has been the driving force of their biological rarity, of adaptation to local conditions, of specialization to isolated environments. After millions of years in isolation, the forces of evolution and fragmentation have yielded unique life-forms in each desert, strangely shaped desert plants and extraordinary animals. The world's deserts are biological and cultural islands, lands of fantasy and adventure, habitats of

surprising, often bizarre growth forms, and territories of immense natural beauty.

Glossary

Ecosystem All the individuals, species, and populations in a spatially defined area and the interactions among them and with the abiotic environment.

Ecosystem functioning The sum total of processes such as the cycling of matter, energy, and nutrients operating at the ecosystem level.

Functional group A group of species that perform similar roles in an ecosystem process.

Nutrient cycle (or biogeochemical cycle) The repeated pathway of mineral elements, such as carbon, nitrogen, phosphorus, and water from the environment through organisms and back into the environment.

Succession The predictable change in species that occupy an area over time caused by a change in biotic or abiotic factors benefiting some species but at the expense of others.

Development of the Ecosystem Concept

The concept of the ecosystem as a functioning unit in the natural world is a relatively recent one. The term ecosystem was coined by the British ecologist Tansley in 1935 and has since then become a common word in science and with the public. An ecosystem encompasses all the organisms of a given area and their relationships with one another and the physical or abiotic environment. The ecosystem contains the linkages and dynamic interactions between life and the environment, many of which are essential to society. A focus on the ecosystem as the unit of study represents a shift from studying the ecology and behavior of individual organisms and species (natural history) to the study of processes and how they influence or are influenced by organisms and their interactions with the environment.

Dividing the complexity of nature into convenient units of study is required for scientific investigation but can present problems. Ecological systems can be organized in a hierarchy of increasing levels of organization and complexity: individual, population, species, community, ecosystem, landscape, and biome. The size (scale) of an ecosystem is defined by the purposes of the study. Ecosystems may have distinct boundaries as in the case of a lake or a watershed. More often, the boundaries of one ecosystem (a forest) may grade gradually into another (a meadow) across an intermediate area called an ecotone. The ecotone is often a zone of higher diversity because it may be a suitable habitat for species from each of the adjoining ecosystems. At one extreme of scale, the earth is sometimes treated as an ecosystem. At the other extreme, the complex symbiotic community of organisms inhabiting the gut of a termite has all the functional properties of an ecosystem. The definition and delineation of an ecosystem has practical importance because ecosystems are increasingly seen as a functional unit for resource and conservation management purposes. It has become evident that the management of lands for sustained levels of ecosystem services and natural resources requires an understanding of how ecosystems function, how they respond to disturbance, and how the role of biodiversity is regulating their function and stability.

Ecosystem Functioning and Ecosystem Services

Society depends on the functioning of ecosystems for many essential ecosystem services on which we place economic and esthetic values (Daily, 1997; Millennium Ecosystem Assessment, 2005). Ecosystem functioning results from the collective activities of organisms, their life processes (production, consumption, and excretion) and the effects of these activities on the condition of the environment. These functions (services when they provide utility to humans) include production of food, fuel, and fiber, the cycling and purification of water, and the maintenance of organisms that have a role in ecosystem functioning or that provide products for human use (Table 1). Humans are rapidly changing the earth's ecosystems and their services by altering land use or by harvesting biological resources (forest cutting and fisheries) (Vitousek *et al.*, 1997a). Approximately 40% of the earth's primary production is diverted to human use. One consequence of these economic activities is an abrupt increase in the rate of change in biological diversity leading to species extinction, replacement of high-biodiversity ecosystems with less diverse managed

Table 1 Examples of the biological and physical processes or interactions that contribute to important ecosystem functions

Process	Ecosystem function
Photosynthesis	Primary production
Plant nutrient uptake	
Microbial respiration	Decomposition
Soil/sediment food web dynamics	
Nitrification	Nitrogen cycling
Denitrification	
Nitrogen fixation	Hydrologic cycle
Plant transpiration

Soil bioturbation	
Vegetation succession	Biological control
Predator–prey interactions	

systems, and invasions of natural ecosystems by exotic species (Millennium Ecosystem Assessment, 2005). This pattern of ecosystem change has raised serious concern that the functioning and stability of our global ecosystem are threatened by the loss of biodiversity.

What Do Ecosystem Scientists Study?

Ecosystems share certain characteristics and functions that allow scientists to study ecosystem types (e.g., deciduous forest, temperate grassland, arctic tundra, coral reef, and deep-ocean hydrothermal vents) that vary greatly in structure, biodiversity, and spatial extent. For example, all ecosystems require inputs of energy (usually solar) and a supply of the mineral elements (nutrients) essential for life. These inputs support many ecological processes operating at multiple scales. For example, sunlight, carbon dioxide, and water are inputs for the process of photosynthesis, which can be measured and studied at the scale of individual cells, a leaf, the plant canopy, or an entire ecosystem. Photosynthesis acting with other processes such as mineral uptake by roots combine to create an ecosystem function – primary productivity.

Scientists can discover basic principles about the behavior of ecosystems by studying the functions that very different ecosystems, such as the polar desert of Antarctica and the rangelands of the southwestern US, share in common (Virginia and Wall, 1999). The movement of energy and materials within and between ecosystems and the role of organisms in mediating these processes are the parameters used by ecosystem scientists to compare the functioning of ecosystems and their responses to disturbance. Some of the important processes and functions central to the integrity and sustained activity of an ecosystem are summarized in Table 2. Ecosystem scientists study the rate at which ecosystems remove carbon from the atmosphere by photosynthesis, store it in the soil as organic matter, and then return the stored carbon to the atmosphere during decomposition. They study how nitrogen is cycled through ecosystems to sustain continued plant productivity. Our knowledge of how carbon and nitrogen move in the ecosystem helps us to understand when an ecosystem has been seriously altered by humans, for example, by adding nitrogen in the form of air pollution (acid rain) and fertilizers.

Many basic principles provide insight into the functioning of ecosystems and their response to human use and

disturbance. Here, we will consider some of the essential functions of ecosystems and examine the principles that govern their operation, with an emphasis on the role of organisms (biodiversity) in determining ecosystem functioning.

Important Ecosystem Functions

Ecosystem Productivity

A central process of most ecosystems is photosynthesis, the capture of solar radiation, and its conversion to stored chemical forms (biomass). Plants require sunlight, water, and essential nutrients for the process of photosynthesis. Photosynthesis is coupled with other plant processes that result in plant growth, for example, the accumulation of biomass. Primary productivity, the change in plant biomass per unit area and time, is an important index of ecosystem function. Primary productivity (often referred to as ecosystem productivity) has been related to plant species diversity as well as the diversity of organisms (soil biota) that influence the availability of limiting resources. Humans depend on ecosystem productivity as the basis of our agriculture, forestry, and fisheries. Thus, factors that alter ecosystem productivity (for example, climate change and biodiversity loss) affect us directly.

Ecosystems with high rates of primary productivity have favorable amounts of resources required for plant growth and optimal climate. These systems also tend to have higher diversity (Table 3). The highest rates of terrestrial ecosystem productivity are seen in the tropics, where temperature and moisture are favorable for plant growth throughout the year. In contrast, water-limited hot and cold deserts have much lower productivity, averaging less than 10% of that of tropical systems.

Limits to Ecosystem Productivity

A basic principle invoked to explain variation among ecosystems in their productivity is Liebig's Law of Minimum. Justus Liebig formulated this concept during pioneering studies of the mineral nutrition of plants in the early 1800s. He found that addition of a single "limiting element" to a soil would increase plant growth. Once this element was in sufficient supply, another mineral element would have to be supplied in increased amounts to stimulate additional increase in plant growth. From these observations, he proposed that a limiting factor was responsible for limiting the growth or reproduction of an organism or population. This factor

Table 3 Typical values for the net primary productivity of major ecosystems^a

Ecosystem type	Net primary production (g C/m ² year)	Relative species diversity
Tropical rain forest	900	Highest
Temperate forest	540	Intermediate
Grassland	315	Intermediate
Desert	32	Low
Extreme desert	1.5	Lowest

^aEcosystem productivity and biodiversity are often positively related.

might be a chemical factor (a growth-stimulating nutrient such as nitrogen), a physical factor such as moisture, or a biological factor such as the presence of a competing species. Thus, any change in a limiting factor is expected to have large effects on ecosystem functioning.

There are many examples in which a change in a limiting factor alters ecosystem function. The large increase in the amount of nitrogen cycling in the environment from fertilizers and fossil fuel should have significant effects on rates of ecosystem functions since nitrogen frequently is the primary limiting element for plant growth in terrestrial ecosystems. Humans have doubled the rate of nitrogen inputs to ecosystems with increases in carbon storage and declines in biodiversity (Vitousek *et al.*, 1997b). In fact, the forests of the northeastern US may have reached “saturation” in their ability to absorb and retain anthropogenic inputs of nitrogen. The limits to production in ecosystems may also be related to the balance (ratio) of essential elements for growth (C:N:P). This theory of ecological stoichiometry predicts that there are multielement constraints on ecological interactions such as energy flow in food webs, competition, herbivory, and on ecological processes such as primary production (Sternier and Elser, 2002).

Are plant species diversity and primary production related? Ecologists are accumulating evidence from experiments in controlled growth facilities and in the field that ecosystem primary productivity increases with increasing plant species diversity. The theoretical basis for the expectation that productivity and diversity should be related derives from an understanding of how limiting resources (water and nutrients) are distributed in ecosystems and an appreciation for the diversity of physiological or “functional” traits that organisms have evolved to capture and utilize these resources for growth. Differences between plant species in rooting depth, phenology (seasonality of growth), photosynthetic rates, and other physiological traits allow multispecies communities to more fully utilize the available resources.

The ability of diverse plant communities to obtain higher productivity than low-diversity systems is demonstrated in traditional (low-input) agriculture in which polycultures (multiple-species plantings) often have higher yields than single-species plantings (monocultures) (Gliessman, 1998). For example, corn (*Zea mays* L.) yields at comparable densities are higher when corn is grown in the presence of nitrogen-fixing beans (*Vicia* spp.). The bean crop forms a symbiotic association with bacteria that “fix” atmospheric nitrogen (N_2) to an inorganic form (ammonia, NH_3) useable by plants. The nitrogen fixed by the bean crop improves the overall supply of this limiting element in the soil and increases the growth of the interplanted corn. The functioning provided by the diverse corn–bean–nitrogen-fixing bacteria association is often replaced in intensive agriculture by applying inorganic nitrogen fertilizers. With external inputs (fertilizers) the corn monoculture can produce higher yields than the polyculture. Substituting an industrial source of nitrogen for a biological source has environmental costs resulting from the production and combustion of fossil fuels used to produce fertilizers and pesticides (Mäder *et al.*, 2002). In addition, over application of fertilizers and pesticides are a major source of water pollution in surface and groundwaters.

There are similar examples of diversity influencing productivity in natural ecosystems. In a California grassland ecosystem, Hooper and Vitousek (1997) manipulated the number of plant functional groups in a community (early versus late-season forbs, perennial grasses, and nitrogen-fixing plants) in combinations of one to four groups in a given plot. They found that the number of plant functional groups was not the main factor that determined productivity. Rather, certain functional characteristics of individual species within functional groups contributed more to ecosystem productivity than overall diversity of the plot. This study points to the complexity of trying to simply relate species diversity to function. As a general principle, ecologists recognize that some species play particularly important roles in regulating important ecosystem functions such as productivity and nutrient cycling.

Keystone Species

Certain species, termed keystone species, have a disproportionate influence (relative to their biomass) on ecosystem functioning. The loss of a keystone species will produce a cascade of effects on the diversity and function of the remainder of the ecosystem (Menge *et al.*, 1994). Consequently, since keystone species can control ecosystem diversity and associated ecosystem functions, they and the habitats they live in often receive high priority in conservation management plans. There are many well-documented studies of keystone species and how they interact with ecosystem functioning, for example, the North Pacific sea otter preys on sea urchins, which consume kelp. In the absence of the keystone predator, sea urchin populations increase and create areas devoid of kelp and, consequently, the myriad of fish and other species that depend on the kelp forest (Figure 1). This is an example of a food web – the

Figure 1 The influence of a keystone species on the biodiversity of an entire ecosystem can be large. Arrows indicate an increase or decrease in population size or species diversity in response to the presence or absence of the keystone species. The removal of the Pacific sea otter from California coastal ecosystems leads to the loss of the kelp community and many fish species.

representation of trophic (feeding) relationships between species in an ecosystem.

There are many examples of keystone species in terrestrial ecosystems. A large change in the number of African elephants has dramatic effects on the diversity and structure of the vegetation types (savanna woodlands and forests) they consume, altering ecosystem productivity, soil nutrient cycles, and plant community diversity. The much smaller tsetse fly shares the elephant's habitat and also has the attributes of a keystone species. The tsetse fly is the vector for the human disease sleeping sickness (African trypanosomiasis). This biting fly also influences the behavior of large herbivores that tend to avoid heavily infested areas. Consequently, herbivore-related impacts on plant communities and associated ecosystem functions are altered in tsetse-occupied ecosystems. This small insect may control the biodiversity of large tracts of Africa through another mechanism. Diverse native ecosystems have been "protected" from agricultural development and species loss because humans avoid regions where the tsetse and therefore sleeping sickness are endemic.

Nutrient Cycling

The sustained functioning of any ecosystem requires a minimum number of species to develop the intricate relationships between producers, consumers, and decomposers that regulate the flow of energy and nutrients. The productivity of all ecosystems is dependent on the cycling of essential elements. The movement and biological transformations of organic matter and nutrients are mediated by biota, especially those found in soil and sediments (Wall and Virginia, 1997). Therefore, changes in the biodiversity of ecosystems can alter biogeochemical processes.

Succession

Scientists study the process of ecological succession (ecosystem change with time, often in response to disturbance) in part to untangle relationships between biodiversity and function. Although not all ecosystems follow a predictable pathway as they develop in time, examples of succession highlight the linkage between organisms, diversity, and ecosystem function. They include the recovery of a forest after harvest or following damage by a hurricane, the reestablishment of grassland following fire, and the old-field succession of natural vegetation reclaiming abandoned agricultural land. During succession, ecosystems change in generally predictable ways as they accumulate species, increase in biomass, and gain structural complexity. Odum (1969) proposed a model of ecological succession (development) that relates ecosystem diversity, structure, and functioning as ecosystems redevelop and "mature" following disturbance (Table 4). Odum's model related the stability (constancy) of function and the conservation of nutrients to increasing diversity – themes that are at the center of biodiversity and ecosystem research today.

The relationships represented in Odum's (1969) model between ecosystem function and diversity are elucidated in the Hubbard Brook watershed experiment (Likens and Bormann, 1995). One of the first long-term ecosystem studies, the Hubbard Brook project began in 1963 in the White Mountains of New Hampshire. The study was designed to

Table 4 A model of ecological succession showing relative changes in energy flow, nutrient cycling, and diversity over time

Ecosystem trait	Ecosystem status	
	Developing	Mature
Energetics		
Net primary production	High	Low
Food chains	Linear	Weblike
Communities		
Species diversity	Low	High
Nutrient cycling		
Mineral cycles	Open	Closed
Nutrient conservation	Poor	Good
System dynamics		
Stability	Poor	Good

understand the process of forest recovery following harvest with a focus on ecosystem functions related to production, nutrient cycling, and nutrient loss. Measurements of the mature intact deciduous forest showed that less than 0.1% of the nitrogen contained in living forest biomass and dead organic matter in the soil and litter left the site in stream flow. A nutrient cycle in which outputs are low and internal recycling of nutrients is high (the loop from soil to vegetation and back to soil) is called a closed nutrient cycle.

After the unperturbed patterns of growth and nutrient cycling were known, an entire Hubbard Brook watershed was clear-cut, followed by a dramatic change in ecosystem functioning. Stream flow increased by approximately 40% because water used by plants had been nearly eliminated by the forest harvest. The previously "closed" nutrient cycle of this forest became "open." After clear-cut, the concentrations of nitrogen (nitrate, NO_3^-) in the stream water draining the watershed increased approximately 60-fold. Concentrations of elements that are important to the biology of the ecosystem leaked into the streams and were exported from the ecosystem. Elements not essential for plant growth or required in very small amounts (e.g., sodium) were not lost to the same degree, indicating their cycling was not regulated by biotic activity of the forest. Odum (1969) predicted that nutrient losses would decline with increasing plant biomass and function. After the Hubbard Brook forest was allowed to regrow (undergo succession), nutrients resumed being absorbed by plants and nutrient losses to streams declined to near baseline levels. The Hubbard Brook ecosystem experiment informed forest management practices by providing a better understanding of how forest removal and regrowth affect the retention of soil nutrients and therefore the long-term productivity and diversity of the ecosystem.

Ecosystem Stability

Ecosystems are dynamic. They experience change in species composition and function in response to variations in climate and an array of disturbances. Fire, flood, drought, frost, and biological events such as the outbreak of pathogens and pests can "stress" ecosystems and alter their condition. Ecosystems vary widely in their responses to disturbance. The ability of an

ecosystem to withstand stress without a loss of function (resistance) or to recover rapidly from disturbance (resilience) is an important ecosystem trait. Some ecosystems appear very stable (high resistance and resilience) and their functioning is little affected by variations in factors external to the system. Ecosystems with high resilience are buffered against perturbation. Many ecosystems, however, show large decreases in productivity and biodiversity when disturbed. These ecosystems are “fragile” and have low resistance.

The relationship between ecosystem stability and diversity has been the subject of many field studies and theoretical tests using mathematical modeling. Ecologists have hypothesized that ecosystems with high biodiversity are more resistant (will experience less change) in response to a given level of disturbance and will also exhibit resilience – a high rate of recovery to predisturbance functioning (Folke *et al.*, 1996).

Does diversity influence the stability of ecosystem functioning? There is experimental evidence that it can do so (Chapin *et al.*, 1998). Several mechanisms have been proposed and tested to varying degrees to examine this relationship. Higher species diversity means that the trophic structure (feeding relationships among species) of the ecosystem is more complex, providing alternate pathways for energy flow within and between trophic levels (producers, consumers, and decomposers). Alternative pathways for energy transfers within the ecosystem could increase resistance to disturbance (species loss). Naeem and Li (1997) tested the hypothesis that redundancy (multiple species with similar functions in a food web) would stabilize ecosystem functioning by creating experimental microcosms with a varying number of species in each functional group. The simple systems contained producers (algae), decomposers (bacteria), and a primary and secondary consumer trophic level (protists) – the trophic structure of a typical aquatic ecosystem. Nutrient levels, light, and the number of species per trophic level were manipulated, and the biomass and density of the producers and decomposers were measured as indicators of ecosystem functioning. As the number of species in a trophic level increased, the biomass and density of replicate communities were more consistent. Thus, the communities with more species were more predictable in function (biomass production) and had higher reliability, i.e., the probability that an ecosystem will provide a given level of performance over a specified period of time. In contrast, the functioning of low-diversity ecosystems may be highly susceptible to decreases in biodiversity or species abundance. In the McMurdo Dry Valley polar desert ecosystems of Antarctica, a population decline in the dominant soil nematode *Scottnema lindsayae* was predicted to cause a 30% decline in soil carbon cycling function (Barrett *et al.*, 2008).

Higher species diversity may ensure functioning by reducing the risk of invasion by species that have the capacity to alter the structure or function of the ecosystem. An example is the higher resistance of species-rich natural systems to pest outbreaks compared to low-diversity agricultural ecosystems growing under the same environmental conditions. The spatial arrangement of individuals in an ecosystem can affect their risk to disease, predation, or consumption. In higher diversity systems the mean distance between individuals of the same species is on average greater than that of low-diversity systems.

The wider spacing of individuals acts to slow the movement of pathogenic organisms, which should limit the occurrence of pest outbreaks that alter the performance of the ecosystem. These and other observations lead to the general expectation that diversity increases the resistance of ecosystems to disturbance.

The benefits of biodiversity to ecosystem functioning should be multiple since the processes of production and nutrient cycling are coupled by the biological interactions of organisms. The response of a Minnesota grassland to a severe drought (disturbance) illustrates this principle (Tilman *et al.*, 1996). In 1987 and 1988, a drought decreased productivity of the grassland. The species diversity of experimental plots prior to the drought explained the degree of productivity loss. Diverse plots experienced about a 50% decline in productivity, whereas productivity in the least diverse plots declined by more than 90%. The greater resistance of the higher diversity plots resulted from compensatory increases in productivity shown by drought-resistant species. The more diverse plots also had lower concentrations of nitrate in the rooting zone, indicating a more efficient use of this limiting resource.

This experiment demonstrates that species diversity has an effect on productivity and nutrient cycling and that declining species diversity influences these functions. However, we lack an understanding of the mechanisms producing these patterns of ecosystem response to disturbance and biodiversity change. Increasing diversity may increase the chance that a single drought-adapted and productive species will be present in the community, ensuring relatively high productivity. Alternatively, higher diversity may provide for a more efficient utilization of limiting resources, as suggested by the lower soil nitrate in more diverse plots. Before the basic relationships between biodiversity and ecosystem functioning can be more fully formalized, we need more detailed information on the critical levels (thresholds) of diversity associated with specific ecosystem functions and how environmental conditions operating over time alter their relationship (Folke *et al.*, 1996). The ability of societies to adapt to uncertainty from rapid environmental change will require resilience-based ecosystem management strategies that sustain essential ecosystem functions and provide for the delivery of critical ecosystem services (Chapin *et al.*, 2009).

Conclusions

Humans have become major agents of environmental change and influence the biodiversity and structure of ecosystems in many ways. Air pollution, clearing of natural systems for agriculture, forestry and urban development, the spread of exotic species, changes in the composition of the atmosphere, and other anthropogenic influences are altering ecosystem functioning. By changing ecosystem biodiversity and altering the processes that biota mediate, we significantly decrease the ability of ecosystems to provide services and resources for our use. The management of ecosystems for sustained levels of services and the restoration of damaged ecosystems will require greater knowledge about the role that species play in ecosystem functions related to production and nutrient cycling. Although we cannot know with certainty the roles of

most species in ecosystems, it is prudent to assume that the entire biodiversity is essential to ecosystem function and stability, and should be valued and protected.

Glossary

Aerobic In the presence of oxygen.

Allochthonous Imported from outside the ecosystem.

Chemoautotrophy Use of energy-yielding chemical reactions as an energy source for synthesis of organic matter from inorganic precursors.

Compensation depth Depth where photosynthesis and respiration are in balance.

Euphotic zone Water depth with sufficient light for photosynthesis.

Photoautotrophy Use of light as an energy source for synthesis of organic matter from inorganic precursors.

Production Newly formed biomass of a population or trophic level, including the organic matter eliminated during the period of observation.

Trophic level Position in a food chain, defined by the number of energy transfer steps to that level.

Trophogenic region Region where net production of organic matter occurs by photoautotrophy or chemoautotrophy.

Tropholytic region Region where respiration and decomposition of organic matter proceed in the absence of primary production.

Conceptual Framework

Biological mass flux and energy transfer obey the first law of thermodynamics. Investigations that follow this theme require basic accounting for inputs and outputs balanced on carbon mass, nitrogen mass, or the chemically bound potential energy present in organic matter. The different bases for accounting are interlinked by the common stoichiometry of all protoplasm. As Alfred Redfield and his colleagues began to point out in the 1930s, there are consistent ratios among carbon, nitrogen, and phosphorus in living matter drawn from lakes and oceans. The ratios are not as rigid as the elemental composition of a crystalline mineral, but they are reliable within limits. They stem from the fact that organisms exist as biochemical aggregates of proteins, lipids, carbohydrates, and nucleic acids. The basic biochemical building blocks are universal, so the scope for differences among species is limited. If a class of organisms dominates the organic nitrogen pool within an ecosystem, it likely dominates in terms of organic carbon or calories as well. Thus the different measurement bases converge to common results.

The energy and mass-based approaches offer consistency of accounting, but they are inherently abiotic. They are indifferent to the forces that govern self-propagating organisms with heritable traits, for which the law of natural selection is as important as the laws of thermodynamics. Survival, persistence, and production of viable offspring are properties that define successful species, whether or not they dominate ecosystem biomass and material flux. Another theme in measuring ecosystem function focuses on the properties of genetic entities rather than on the properties of conservation laws. This second theme focuses on processes that add or subtract individuals or genomes within an ecosystem, processes such as birth, death, or migration, as well as the explicit match between individual age and the passage of time. Viewed through a lens that traces heritable lines of descent, mass and energy transformations are incidental consequences. Transformations of energy and material are the byproducts of life struggles whose object is indefinite persistence.

In 1961, Hutchinson coined the phrase “paradox of the plankton” to define the challenge to explanation presented by the species diversity of plankton communities. Nets towed from several hundred meters depth to the surface in the Pacific Ocean north of Hawaii, for example, routinely collect more than 300 species of zooplankton, and the richness of phytoplankton species in the surface waters is equally great. The oceanic pelagic region is the oldest continual habitat on the planet and its denizens are the product of ceaseless natural experiments. Near coastal regions and in lakes and rivers, the permanent plankton are joined by the larvae of benthic organisms. To Hutchinson, the contemporaneous existence of so many distinct genetic lines in habitats that lack obvious structural complexity begged important questions about coexistence, interactions, competition, and resource use. Faced with a bewildering array of potential species interactions, investigations of the marine pelagic ecosystems historically have emphasized mass and energy flow rather than individual species dynamics. Compounding the problem of overwhelming diversity is the fact that marine plankton are notoriously difficult to census accurately, owing to the physical movements of water masses, to such an extent that some workers believe that time series data that are essential to population studies are nearly impossible to gather.

In an effort to span the breach between measurements of organic composition in units of carbon or nitrogen and the realities of the ways matter is packaged as individual organisms, there has been great interest in finding rules of general validity and broad predictive strength that blend the approaches. Special attention has been paid to relationships based on individual body size or biomass. These size-based or allometric models of ecosystem processes offer the attraction of predicting metabolic rates and trophic interactions from simple measurements. Extensive tabulations have become available for physiological processes such as respiration, motility, body growth, and feeding rates versus individual size. This activity has spurred the drive toward models of ecosystem dynamics that treat the size structure of organisms present in a system more so than the phyletic composition of the communities.

Biological Comparisons Between Freshwater and Marine Ecosystems

Freshwater ecosystems exhibit reduced species richness compared with marine systems. Many important invertebrate groups (e.g., Echinodermata, Ctenophora, Chaetognatha) have failed to colonize freshwater habitats, although in some cases their roles have been assumed by successful radiation of aquatic insects, particularly the Diptera, in lakes and streams. Much of the difference may be owed to the greater depth, antiquity, and continuity of oceanic plankton environments. The role of age alone is problematic, however. The great ancient lakes of the planet such as Baikal, Tanganyika, and Malawi, with basin ages measured in hundreds of thousands to a few millions of years, exhibit endemic species radiation of some groups but not all. The zooplankton faunas of the ancient lakes are notably undiversified, despite rich endemism among some fish, mollusks, or amphipods.

Not only are there differences in overall species richness, but there are some differences in latitudinal trends as well. In general, the diversity of marine plankton is greater at low latitudes than at high latitudes. The latitudinal trend in species richness for freshwater plankton is the opposite. Tropical lakes have abbreviated zooplankton faunas compared with temperate sites. The tropical lakes are depauperate of large-bodied Cladocera and copepods, but they are poor in small-bodied pelagic rotifers as well.

Primary Production

A basic unit of measurement, and also a fundamental basis for comparisons among aquatic ecosystems, is the rate of primary biological production. Several methods are used (Vollenweider, 1974; Lampert and Sommer, 2007), but they rely on the overall chemical reaction of carbon fixation in photosynthesis:

where A represents an element that serves as an electron donor for the photochemical oxidation-reduction reaction. In photoautotrophic reactions of algae and bacteria in lakes and oceans, oxygen, sulfur, or reduced organic compounds are used as the electron donors. Methods for measuring primary production differ depending on whether the focus is on the transformation of inorganic carbon into organic matter, the resulting release of oxidized product, or changes in the internal cellular redox system or photochemical state. The different methods are not equivalent, and the stoichiometry of carbon fixed to oxidation product released is not strictly 1 to 2 as indicated in eqn [1]. Equation [1] is a simplification of the true synthetic reactions involved with cellular growth. Synthesis products are not only hexose sugars, but include all sorts of carbohydrates, as well as proteins, lipids, and nucleic acids. The photosynthetic quotient (PQ) of oxidized product released to carbon fixed varies according to the dominant synthesis products.

In practical application, measurement of primary production relies on one of two approaches. Either measurements are made on subsets of the natural community, which are

enclosed and isolated for an experimental time duration, or the measurements are made directly on the natural community without isolation. Both approaches have advantages and potential complications.

Oxygen-Based Methods

To avoid the complexity of diffusion or advection of dissolved substances and gases in or out of a water parcel, most measurements of primary production are conducted in enclosures. During the 1920s, oceanographers introduced one such method that is still in wide use: the light and dark bottle oxygen method. The method relies on making three measurements of oxygen concentration: (1) the initial concentration of dissolved oxygen in a water sample at the start of the experiment, (2) the final concentration of oxygen in a water sample that was enclosed in a transparent bottle called the Light bottle, and (3) the final concentration of oxygen in a water sample enclosed in an opaque bottle called the Dark bottle. From these three experimental measurements it is possible to deduce rates of respiration (R), gross primary production (GPP), and net primary production (NPP):

$$R = ([\text{O}_2]_{\text{Initial}} - [\text{O}_2]_{\text{Dark}}) / \Delta t \quad [2]$$

$$\text{GPP} = ([\text{O}_2]_{\text{Light}} - [\text{O}_2]_{\text{Dark}}) / \Delta t \quad [3]$$

$$\text{NPP} = ([\text{O}_2]_{\text{Light}} - [\text{O}_2]_{\text{Dark}}) / \Delta t \quad [4]$$

where Δt is the duration of the incubation. The experimental bottles are either suspended at specified depths in the water column at the sampling site for duration of the experimental incubation, or they are placed in light and temperature conditions that simulate submarine conditions. The duration of experimental incubation Δt is invariably a compromise between the desire to obtain measurable changes in oxygen concentration and the desire to minimize artifacts resulting from prolonged exposure, such as growth of microorganisms on bottle surfaces or development of supersaturated oxygen concentrations inside the bottles. Typical incubation durations range from 4 to 24 h.

Carbon-Based Methods

Methods that record fixation of inorganic carbon into organic matter rely either on measuring the removal of inorganic carbon or the appearance of new carbon in the organic matter. The pool of inorganic carbon available for photosynthesis in aqueous solution includes not only dissolved aqueous carbon dioxide, but also the reaction products of carbon dioxide with water molecules. Carbon dioxide reacts with water to form carbonic acid:

Carbonic acid is a weak acid that dissociates to form its conjugate bases bicarbonate and carbonate:

At equilibrium conditions the concentration ratio of dissolved aqueous carbon dioxide to carbonic acid is about 600 to 1. Proportions of carbon dioxide to bicarbonate to carbonate vary widely, but at the environmental pH of the ocean and many lakes, bicarbonate concentrations exceed all other molecular carbon species. The pool of dissolved inorganic carbon (DIC) available for photosynthesis is defined as

$$\text{DIC} = \text{CO}_2 + \text{HCO}_3^- + \text{CO}_3^{2-} \quad [8]$$

The three dominant chemical species that comprise DIC exist in known stoichiometric relationships to each other as functions of pH, temperature, and ionic strength of the aqueous solution. There are several ways to measure or calculate DIC. An aqueous sample may be acidified, transforming all DIC to carbon dioxide, and the resulting gas can be measured. Alternatively, pH and CO_2 may be measured and then the other species are calculated. Or the concentrations of the conjugate bases can be measured by acid titration, and from their total plus measured pH, the DIC is calculated.

C-14 Method
